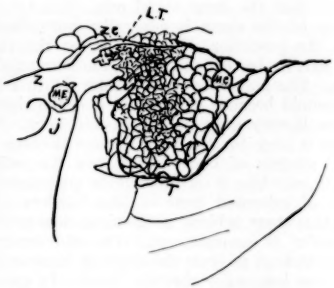
In a completely sclerosed mastoid no cells whatever can be seen. The bone looks smooth and dense. The meatus and middle ear are seen as in normal mastoids as a less dense area. Usually the antrum shows as a mottled area just above and posterior to the meatus. The lateral sinus generally shows very distinctly in this type of mastoid. The more dense the sclerosed bone and the longer it has existed, the more distinctly does the sinus stand out. The anterior border of the sinus is generally more distinct than the posterior. In some cases the latter can hardly be defined from the surrounding bone. The sinus shows so clearly in this type of mastoid because of the fact that the sigmoid groove is very deep in the mastoid bone. This makes it easy for the rays to pass through the small amount of bony cortex over the path of the sinus while it is difficult to penetrate the mass of sclerosed bone on the borders. The fact that there is blood in the sinus does not help to make it conspicuous. On the contrary, it would tend to limit the contrast because light can pass less easily through blood. In cases of cellular mastoids, the dense borders are replaced by cells which obstruct the rays very little and this explains the inconspicuousness of the sinus in the normal mastoid. The position of the sinus varies in the different cases and the position in the plate is of some value to the surgeon before operating. One cannot lay a measure on the plate and say that the sinus is just so many millimeters posterior to the posterior wall of the canal. The projection so measured would be deceptive for several reasons. First, the Röntgenologist may have placed the heads at slightly different angles, or the shape of the individual head made this imperative. The course of the sinus not only varies, as seen in a lateral projection, but may be nearer the surface in some cases than in others. The more marked the light penetration over the sinus, the more superficial it must be. The more acute the angle at the knee (junction between sinus proper and sigmoid portion), and at the same time superficial and projected close to the posterior wall, the more troublesome it will prove while excavating a passage to the antrum. In some cases the anterior wall of the sinus can be seen projected over the posterior and inferior portion of the antrum and in such cases the sinus is liable to be uncovered before reaching the antrum.

Some sclerosed mastoids, especially the larger ones, occasionally show a large area about the antrum or extending down toward the center which is less dense and mottled in appearance. At operation such a mastoid is found to be broken down with areas of pus, granulations of cholesteatome. Sometimes a distinct cholesteatome cavity may be seen.

The appearance of the tip of a sclerosed mastoid which dates from infancy is often characteristic. As had been said, the tip cannot be developed by budding cells from the antrum nor can it be filled in by regenerated bone after destruction of the existing cells as in cases in which the sclerosing process started later in life. In these cases the tip is densely sclerosed but has fine wavy lines, as is seen in ivory. This appearance has been interpreted as diploëtic but is not found so at operation. These cases give the best detailed pictures and at times the mastoid vein and foramen is seen and on two occasions the Fallopian canal could be made out. A line of fracture through the mastoid was shown clearly in a plate and later was demonstrated by operation.

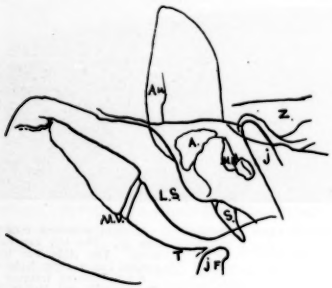


There is one type of case that has not yet been spoken of, namely, the so-called effectus ear. By that term is meant any ear which shows by scars or perforation of the drum membrane that there has been a past suppuration. An X-ray plate of such an ear shows all degrees, from a normal cellular mastoid, partly cellular, semi-sclerosed to a completely sclerosed mastoid. the same patient may have a sclerosed mastoid, on one side and a semi-sclerosed or normal mastoid on the other and yet both ear drums are effectus and there is history of past ear trouble. This observation may be easily explained. It is well known that a mild acute ear can cause a scar by rupture of the drum or by having a paracentesis done, suppurate for a short while and then dry up without distinctive involvement of the mastoid and yet be classified as an effectus ear. Had this process gone farther before clearing up there would have been more damage to the drum and the mastoid would have been structurally altered. Partial sclerosis, which always advances from the periphery, would have resulted. The cells remaining were either uninjured cells that escaped the suppuration or a regeneration of cells, the latter having been observed clinically by others. The fact has been known clinically that a discharge existing for years in a chronic suppurative ear may cease and the drum cicatrize and in these cases is to be found the explanation of the sclerosed mastoid seen in an effectus ear. Nothing shows more clearly than X-rays of effectus ears the varying degrees in which suppurations in the middle ear affect the mastoid structure.

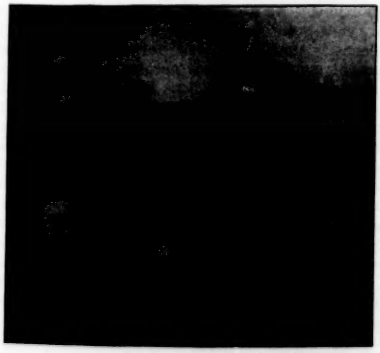
The following more detailed statistics may be of interest. The total number of mastoid pictures tabulated was 460. Many others were discarded either because the plates were poor or because of insufficient data. The number of pathological mastoids was about evenly divided between the right and left sides. There were many more sclerosed mastoids on the right side

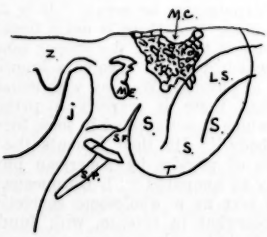
than on the left but the number of acute mastoids on the left side equalized the division. This coincides with the records of the mastoid operations performed at the Infirmary for the past ten years. Although one side may prevail over the other for a given period, the average is about the same for each side.

In cases where the clinical diagnosis of chronic suppurative ear was made, 94% showed total sclerosis of the mastoid and 6% semi-sclerosis. In the cases where a diagnosis of effectus ear was made, 56% were totally sclerosed, 27% semi-sclerosed, and 17% were cellular or normal. In cases where no diagnosis of a past or present suppurative process was made, 92% had normal mastoids and 8% were sclerosed or semi-sclerosed. 10% of the cases diagnosed as acute suppurative otitis media showed sclerosed or semi-sclerosed mastoids. These represent the cases of acute processes superimposed on an effectus ear, or the acute exacerbation of a chronic ear. These latter are often difficult to differentiate clinically. The conditions found at operation were compared with the clinical and x-ray diagnoses in seventy-five cases.



A left normal cellular mastoid. Female. Age 26. The right mastoid was sclerosed from a chronic suppurative ear of 12 years' duration.
M C, mastoid cells. Z C, zygomatic cells. Z, zygoma. ME, middle ear and canal. j, ascending ramus of lower jaw. T, mastoid tip.





A right acute destructive mastoiditis. Male. Age 48. A discharging ear for two months.
T, remains of mastoid cortex at tip. F, homogeneous area where all cellular structure is replaced by pus and granulations. C, mottled area suggesting some remnants of cellular structure bounded above by the linea temporalis. P A, shadow due to postaural abscess and granulations over the sinus. j, ascending ramus of lower jaw. Au, auricle. At operation there was found a postaural abscess, perforation of the cortex and the mastoid filled with pus and granulations. Some cellular structure was found about the antrum.

A right sclerosed mastoid. Female. Age 12. The left mastoid was similarly sclerosed and verified at operation. Both ears had discharged since five years of age.
Au, auricle. L S, lateral sinus. S, styloid process. Z, zygoma. j, ascending ramus of lower jaw with the articulation. M E, middle ear. M V, mastoid foramen and vein. T, sclerosed tip. jF, jugular foramen. A, less dense area in sclerosed bone suggesting site of antrum.

A left semi-sclerosed mastoid. Male. Age 50.
M E, middle ear and canal and shadow of maleus. Z, zygoma. j, ascending ramus of lower jaw. M C, remnants of some ill-defined mastoid cells. L S, lateral sinus. Posterior border not distinct. S S S, sclerosed area. The wavy ivory-like structure is visible in the negative. T, mastoid tip. S P, styloid process. S F, stylo-mastoid foramen and Fallopian canal.

A right sclerosed mastoid showing a line of fracture. Male. Age 36. The left ear was an effectus ear and the mastoid sclerosed. The right ear had discharged for three weeks and the patient had a right facial paralysis for that length of time. F F F, line of fracture from the occipital suture (S F) across the mastoid and facial ridge (F R). S A, softened area in the mastoid. S S, sclerosed area. T, mastoid tip. L S, lateral sinus. L T, linea temporalis. Z, zygoma. j, ascending ramus of jaw. At operation the line of fracture was found in a sclerosed mastoid with a softened and broken-down centre.

LABORATORY PHYSIOLOGY IN COLLEGE AND IN MEDICAL SCHOOL.

BY ARTHUR DERMONT BUSH, M. D., BURLINGTON, VT

Instructor in Physiology, Univ. of Vermont, College of Medicine.

In 1885, Professor John C. Draper of the Medical Department of the University of the City of New York published his highly interesting book entitled "Medical Physics." By way of introduction he says: "It is no exaggeration to say that there is not a tissue, organ or function of the body, the proper comprehension of which does not involve a knowledge of the laws of physics. We may with equal justice affirm that there is scarcely a principle of physics which is not applied in some form in the human body." He then laments the general ignorance of physics by American physicians, especially as compared with Europeans, and offers his text as a wholesome corrective. He deals, somewhat *in extenso*, with fundamental principles, but makes many pioneer applications of these principles to the science of medicine.

Nearly thirty years have passed since this work of Dr. Draper first appeared. During this period the teaching of Physics as a separate subject has been taken up by many schools, carried for a while, and subsequently dropped; not, however, without distinctly affecting methods of teaching. We take note of physical principles in pathology, surgery and hygiene, but more particularly in physiology a greater part of whose manifestations are simply physical. Yet in these several branches of medicine, use is made chiefly of such of the data of physics as are directly applicable; the broad general principles are no longer taught in the medical school. We have come to see that medical science is specific, not general; deals not with the universality of law, but with the operating of universal law under particular, well-defined conditions. As a consequence of this change in our view-point a knowledge of the science of physics is now demanded not as a part of the medical course but as a necessary prerequisite. Knowledge of physical laws is, as Draper urged, essential to the proper comprehension of bodily functions, but that knowledge must be acquired where universals are taught,—in the academic side of the university; whereas a knowledge of the specific applications of those laws to the functioning human body must be learned in that department of the university devoted to the special study of the human body, to wit, in the medical school.

A similar comparison might be drawn from the methods of teaching chemistry. Not so many years ago, nearly all schools used valuable time teaching medical students fundamental principles in chemistry:—the laws of chemical combination and dissociation, nomenclature, periodicity, atomic theory, reactions and compounds of the metals and non-metals. Today, however, all of this general knowledge must be acquired before entering the medical school; and we are looking forward to the time when organic chemistry together with qualitative and quantitative analyses will also be a part of all premedical courses. Here again we recognize the principle that knowledge of general application should

be acquired in the academic side of the University; in its place in the medical school we are to teach the application of those general laws in the determining of the problems of human metabolism, in investigating physiologic and pathologic analyses and syntheses, and in estimating all those chemical reactions characteristic of bodily activity.

Since we have accepted this welcome readjustment in the departments of physics and chemistry (moved somewhat hurriedly albeit tardily thereto by the suasion of the Council on Medical Education), why should we not continue the good work in other departments, notably in the department of physiology? In our medical schools, in the department of physiology, we are giving courses parts of which properly belong to the work of the high school and college. We spend many long hours in the discussion and demonstration of fundamental biological laws (e. g. nerve-muscle reactions), studies as much out of place in the routine medical course as would be discussions of work and energy, motion and force. We seem to assume that there are no other agencies for the teaching of physiology as a pure science, and that, perforce, we must be elementary before we can be advanced. But there exist other excellent agencies for just such elementary training; hence we have no justifiable excuses for allowing our methods to lag ten to twenty years behind the pedagogical spirit of the times. As in chemistry and physics, we should require that all physiological data having a general application be taught in a premedical course, so that time may be reserved in the medical course in physiology for a dealing with data concerning human functioning specifically. "But" urges a highly-respected correspondent "there is no such thing as a human physiology; physiology is the same in frogs and cats as in man." Qualifiedly, yes; when considered as a pure science,—as a problem in biology; but not so when considered as an applied science. Aside from the many variations between physiologies of the higher and lower types, it is also true that in so highly complex a specialty as modern medicine there is a specific physiology—a physiology of the living, human body concerning whose functionings and varied manifestations the medical student needs a profoundly intimate acquaintance. Moreover, true to the growing spirit of teaching universals in the academic side of the university, and applied science in the professional and technical schools, we may ere long do in physiology as we have done in physics and chemistry, and insist on a premedical knowledge of biological principles so that we may utilize the needed time in the medical school for studying the action of those biological laws as manifested in the human organism. Our great obligation in the laboratory of medical physiology is to so train our students in the accurate observation of the multiple manifestations of the activities of the normal human mechanism that, when they enter the department of clinical medicine, they will be able to determine immediately the physiological significance of manifestations indicative of departures from the normal; students so trained would not only instantly recognize morbid conditions but they would, in the great majority of cases, be able to promptly deduce presumptive causal factors, provided, all the problems of the physiological laboratories were studied in the true spirit of investigation.

This unconventional point of view has been presented in general terms by others. Flexner (Bulletin No. 4 p. 59) says: "Physiology and pathology belong, then, in the university, because there is much more to them as sciences than the medical school has time for"; also (p. 60) "Physiology as an element of a liberal education, sweeps the whole horizon impartially, interested in genetic processes, searching for general laws. It works to best advantage with simple forms, . . .with jellyfish and cats in preference to man; an admirable introduction to medical physiology, but not really the same thing." Professor Matthews, of Chicago is quoted by Flexner as believing that both physiology and pathology (presumably, as general sciences) "should follow the example of physics, botany and chemistry and leave the medical faculty and be regarded as subjects prerequisite to the study of medicine" (*ibid* p. 60. Dr. Frederick T. Lewis of the Harvard Medical School takes a different view, a view burdened with some inconsistency. In an article entitled "The Preparation for the Study of Medicine" (Popular Science Monthly, July, 1909, 75, 65) he recommends that the matriculant in medicine should have taken premedical courses in college in zoology, botany, chemistry, physics, psychology, history, philosophy, political economy, English, French, and German. Under zoology he recommends the study of morphology by vertebrate dissection, embryology, histology and microscopic technique; but under the heading of "College Physiology" he says; "Some colleges offer courses in physiology which are dilute presentations of medical school work." "It is wholly undesirable for the medical student to take time from other college work for the sake of such courses." This is remarkable! Why, after recommending morphology, does Dr. Lewis balk at the equally important part of zoology embodied in those manifestations of life constituting physiology? Is not the muscle active as instructive as the muscle dead? Are not the conditions regulating activity as interesting as mere form and position? Or, again, is the study of vertebrate physiology any more of an intrusion on medical work than vertebrate dissection is a substitute for human anatomy? For the sake of sweet reasonableness, let us paraphrase Dr. Lewis' quotation thus: "Our medical schools are offering courses in physiology which, because of their elementary character, belong chiefly to the college," "It is

wholly undesirable for the medical student to take valuable time from his medical course for the sake of courses logically belonging to the academic side." This latter statement is really the text for Dr. Lewis' article (q. v.) for everything except physiology. Why except physiology, or rather that part of physiology which is fundamentally biological in its scope?

To ascertain to what extent the medical school may be duplicating work offered in secondary schools, several high school text-books were examined; and from one (Advanced Physiology and Hygiene, Conn and Budington) the following experiments are selected from the large number given: Experiments on beef heart and valve action; beating heart of frog or turtle; capillary circulation; lacteals in mesentery of cat; ciliary movements in frog; nerve-muscle preparations from gastrocnemius of frog; some characteristics of heart muscle (frog); spinal reflexes (frog); artificial eye; experiments with the "Harvard Apparatus." Are any of these omitted in the medical course?

Furthermore, to ascertain to what extent the subject of physiology is being offered in college, and the adequacy of the college course as a substitute for the biological part of the present course in physiology in the medical school, an inspection was made of the catalogs of about sixty colleges, supplemented by requests for detailed information in a certain proportion of cases. The information gleaned was often unsatisfactory owing to the frequent omission of definite statements as to the actual work done in both the lecture-room and in the laboratory; so it well may be that some colleges giving satisfactory courses are not herein listed. Six colleges, Baylor, Brown, Chicago, Dartmouth, Illinois and Yale give courses in *general* physiology equal or superior to the courses now given in most medical schools. A part of the work at Yale is as follows: "Physiology Chemistry, a course dealing with the chemical side of Physiology. A laboratory fee of fifteen dollars is charged." 12 hrs. 2d half. "Physiology of Nutrition. A course of lectures, recitations, and demonstrations, dealing primarily with the physiology of secretion, digestion, absorption, excretion, metabolism, and other general questions bearing on the subject of animal nutrition." 2 hrs. 2nd half. "Physical and Nervous Physiology. Lectures and recitations (three hours a week) with assigned reading in a text-book, and laboratory work in the mechanics of muscle and nerve, the nervous system, the circulation and respiration." 9 hours 1st half. At the University of Illinois, besides histology, hygiene and research, there is offered in the department of physiology the following: "Major Course.—Physiology of nerve and muscle; circulation; secretion; respiration; digestion; metabolism. Lectures and laboratory. (Full medical credit in physiology)" 2nd semester; 10 hours a week. Prerequisites: General Physics; Chemistry—Inorganic and Organic, Quantitative and Qualitative Analyses, Organic Synthesis; Zoology; Vertebrate, and Comparative Anatomy, Microscopical Technique and General Vertebrate Embryology. So complete are these courses that they are fully accredited in the Medical Departments; a fact which indicates, as the Yale catalog states (p. 143), that these courses in the medical school "are of an essentially biological character." It indicates, furthermore, that we are giving an academic, premedical course in physiology in the medical school instead of the technical course that should be given. What possible excuse can there be for a continuance of this condition? Why devote weeks to biological problems when the time is vitally needed for the training of men to an intimate acquaintance with the problems of human bodily activities? The entire assignment of hours in the department of physiology is none too ample for the acquiring of accurate information concerning the mechanism of the normal human body; and, since departures from the normal constitute the student's future field of investigation, it becomes doubly imperative that his knowledge of the normal be as profound as possible. Time may be spared for no work except the strictly professional, until satisfactory proficiency permits of the assignment of correlated problems. Let no one think that any of this study of the functioning human body may be taken up in physical diagnosis, or in topographical or regional anatomy. The latter is but a necessary preparation for accuracy of work in physiology; and completeness of information in human physiology is the *sine qua non* for success in diagnosis.

Besides the six colleges mentioned above, the following schools give courses which seem to be ample substitutes for the biological work in the medical school: Arkansas, Alabama, Bryn Mawr, Columbia, Cornell, Georgia, Indiana, Kansas, Missouri, Nebraska, Northwestern, Ohio State, Pennsylvania, Princeton, Purdue, Wisconsin and Texas. Again the question may be repeated: With twenty-two schools, at least, giving the biological work in physiology, what excuse can there be for any medical school duplicating the work? Twenty-four other schools offer courses either too elementary, or too specifically correlated with hygiene or with the teaching of physiology in secondary schools, to permit of their being added to the above list. Three schools, Boston University, Johns Hopkins and New York, offer courses in physiology to specials or graduates only. Four schools, Bowdoin, Drake, McGill and Tulane apparently offer no work in physiology. Two, at least, Dartmouth and Leland Stanford Jr. give their course in medical physiology in the academic department, a method quite at variance with the pedagogical principle this paper propounds; while seven, Cincinnati, Harvard, Iowa, Michigan, No. Dakota, Tufts and Utah offer academic physiology in the department of medicine, a method equally at variance with the idea herein

proposed. My premise is that medical education should be strictly technical, whereas the work on the academic side, as Dr. Souchon and others have contended, should be concerned with universals. If this premise be granted, then the medical school has neither the time nor the "atmosphere" for teaching general laws; nor has the academic side the equipment or spirit for teaching specific applications. That such cross teaching is being done today is due chiefly to two causes: (a) identity of subject-matter, and (b) non-recognition of the real difference in purpose of these two departments of the University. It can not be urged too often that the student has a right to the strict technical education that the needs of the community demand. Moreover, as Dr. Lewis urges (ibid p. 74), "In this great pursuit he will not become narrow. He will develop what Dr. James Jackson long ago described as a 'mind liberalized by scientific studies.' If he loses a certain breadth of culture because of specialization, still as Cardinal Newman has said, 'the advantage of the community is nearly in inverse ratio with his own.'"

It is submitted that the following subjects, now a routine part of most physiology courses in medical schools, be relegated to the academic department, where they more properly belong; there to be smelted to such values as may be useful in the development of a broad general course in general physiology: Muscle tissue experiments such as elasticity, extensibility, cohesion, consistency, irritability, contractility, time of contraction, curves, latent periods, phases of shortening and relaxation, isotonic and isometric contractions; variations in strength of stimuli, temperature, and drugs; treppe, contractures, fatigue, curve of work, summation. Electric phenomena, as demarcation current, negative variation, monophasic and diphasic action currents, rheoscopic frog, electrotonus, velocity of nerve impulse, direction of impulse, variations from external factors, refractory period, nature of nerve impulse, trophic phenomena, degeneration and regeneration. Reflex frog. General functions of the spinal cord. Characteristics of heart tissue of the poikilothermous animals. Hematology, capillary circulation, time of circulation, mechanical factors, volume curve. Automaticity of heart, and effect thereon of the salts of Na., K. and Ca. in varying percentages. "All or none" law, refractory period, compensatory pause, normal sequence, cardiac nerves and their action, vasomotor nerves. Principles and mechanics of respiration, chemical and physical changes in respired air and the relation thereto of the diffusion of gases, innervation of respiratory movements, variations from external factors. General physiology of digestion and alimentation, ditto excretion. Physiology of glands. Decerebrate frog, decerebellate pigeon, studies on the semicircular canals of frogs and pigeons and on the saccule and utricle of the *palaemon*. Embryology of the chick and pig; and studies on the growth of chick and pig as affected by variations in alimentation.

These are samples of the subjects now cumbering our routine work in laboratory physiology. No one questions their individual values as items of general physiology, or as topics for assignment in the research laboratories; and it may be admitted that a few may be utilized for purposes of demonstration; but the great mass has no place in a department presumably devoted to the training of men to an efficient knowledge of the functioning *human* body. Such subjects should be taken out of the medical curriculum, and in their stead should be placed studies upon such physiological phenomena as are manifest in, and demonstrable on, the body of a fellow student. To be sure, all known facts cannot thus be studied; some things must be learned by hearsay. The intricate, hidden details will have to be worked out by the specialist in research; his findings will be gratefully accepted by that great body of earnest men who have neither the opportunity nor the economic necessity for such prolonged investigations. However, there is an ample supply of desirable experimental problems; and, since time and privilege are so limited, shall we not rather put our great emphasis on just that data which must inevitably serve as the major premises in all the clinical syllogisms of the practitioner's future?

Why encumber ourselves with the ghosts of the past when once freed from the chains of a halting belief? When the manufacturer of today discovers his plant not running at maximum efficiency, he directs a searching investigation to the end that wornout machines be replaced, antiquated methods be abolished, and systems demonstrably useful be introduced. Shall not the teacher as dispassionately weigh? When he finds himself burdened with excess of demands, unable to accomplish needed results because of the press of conventional tasks, shall he not bravely assume the courage of his convictions and sharpen his scalpel forthwith? The great responsibility of the teaching in the laboratory of physiology is to train the men to observe carefully, record accurately, and deduce logically; and the best data for this supreme work is just that which is of greatest pertinence to the life-work of the physician.

The cases of infectious diseases reported to the Boston Board of Health for the week ending February 24, 1914, are as follows: Diphtheria, 68; scarlatina, 147, of which 14 are non-resident; typhoid fever, 5, of which 2 are non-resident; measles, 61; tuberculosis, 35, of which 2 are non-resident.

The death-rate of the reported deaths for the week was 16.72.

Clinical Department.

THE TREATMENT OF UTERINE CARCINOMA WITH CANCEROUS ASCITIC FLUID.

BY ROBERT M. GREEN, M.D., BOSTON,

AND

FRANK C. W. KONRAD, M.D., BOSTON.

[From the Gynecologic House Clinic of the Boston City Hospital.]

IN February, 1910, the late Dr. Hodenpyl, of New York, first reported[1] his work in the treatment of carcinoma with cancerous ascitic fluid. The somewhat startling success recorded in his early cases aroused great expectations of the possible value of this new therapeutic measure. Unhappily, Dr. Hodenpyl's untimely death prevented the completion of his own experimental researches.

The subject, however, interested many others, and several made similar laboratory and clinical investigations, with varying results. In May, 1911, Risley, of Boston, published[2] a report of his work, done at the Massachusetts General Hospital, under the direction of the Cancer Commission of Harvard University, which may be regarded as the conclusive continuation and completion of Hodenpyl's studies.

Risley described the theory and technic of his procedure, the animal experiments by which he determined the safety of administration of the cancerous fluids, and finally the clinical histories of a series of 45 cases of human carcinoma, which he treated over a considerable period of time with cancerous ascitic fluids from 5 cases. Some of the treatments were with autogenous, the majority with heterogenous fluids.

From a critical and dispassionate study of his results, Risley's conclusion was that "the use of cancerous ascitic fluid from patients in the active or even moderately resistant stages of the disease has no permanent effect in preventing or checking the growth of cancer, or of permanently benefiting the patient. Temporary beneficial effects may be noticed for periods of one to five months, but the course of the disease is in no way permanently retarded. Temporary relief from pain, especially in uterine cancer, and retardation of the growth for periods varying from one to five months may be expected in a small percentage of the cases."

In an appendix, Risley reported in brief a further series of 20 cases similarly treated; and from a further study of them and of his earlier cases concluded that "great symptomatic relief can be obtained in a good percentage of the patients treated, evidenced by relief from pain and improvement in nutrition and general physical condition. Retardation is noticeable and in many cases is prolonged from one to six months."

During the winter following the publication of Risley's article, the present writers had the opportunity of observing several cases of in-operable uterine carcinoma in the gynecologic wards of the Boston City Hospital. In view of the occasional relief from pain and the temporary retardation of growth which Risley had observed in cases of this type, it seemed worth while to make further trial of the method of treatment with cancerous ascitic fluid. An abundance of such fluid was obtained from one of the cases in our series, and with this were made autogenous inoculations in her case, and heterogenous in five other patients. The treatment was continued in some instances over a period of four months. The reporting of this series of cases has been delayed for two years, in order that final results might be recorded, so far as obtainable. For the privilege and opportunity of observing, treating, and reporting these cases, we wish herewith to express our grateful and appreciative acknowledgments to the visiting surgeon and to other members of the staff.

CASE 1. *Gynecological Records,* vol. 165, p. 281. M. G. Aet. 55. A widow. Two previous morcellations for inoperable carcinoma uteri. Patient has had six normal labors at term. Menopause eight years ago. Entered hospital June 5, 1911.

P. E. Well developed, pale and emaciated. Heart and lungs normal. Abdomen presents a sensitive mass, size of a grapefruit, rising above the symphysis, and apparently connected with the uterus. The posterior lip of the cervix is eroded and freely bleeding. Induration of anterior lip extends to and involves the base of bladder. The uterus is enlarged to size described above. Liver enlarged.

Diagnosis. Recurrent general abdominal carcinosis.

This patient remained in hospital 14 weeks. She gradually developed considerable ascites and on Aug. 10, 1911, was tapped and Ov ℥xi of clear greenish fluid withdrawn into sterile flasks. Examination of this fluid showed it to be sterile, with a low specific gravity. Cytologically its centrifuged sediment consisted largely of flat epithelioid cells.

On Aug. 14, 10 cc. of this fluid were injected into the patient's abdominal wall, without local or general reaction. On Aug. 17, 20 cc. were given, and on Aug. 22, 30 cc., both also without reaction.

The patient's condition now became rapidly worse. The ascites recurred, and on Sept. 4 she was tapped of Oxii of similar fluid, which was similarly preserved. The patient died on Sept. 8 without benefit from treatment.

CASE 2. *Gynecological Records,* vol. 167, p. 69. A. D. Aet. 42. Married 15 years. Born in England. Admitted to hospital July 12, 1911.

Obstetrical History. Full term; 6; last in Sept., 1907. Premature, 4. Miscarriage, Feb., 1911. Vaginal discharge, continuous since 1899; slime and blood; medium amount. Pulse, 132; temperature, 100.8°.

Aug. 16, 1911. 5 cc. ascitic fluid into abdominal wall.

Aug. 19, 1911. 10 cc.
Aug. 22, 1911. 15 cc.
Aug. 25, 1911. 15 cc.
Aug. 29, 1911. 15 cc.
Sept. 2, 1911. 20 cc.
Sept. 6, 1911. 20 cc.

Temperature oscillates between 98° and 100° but no change can be noticed as referable to the injections.

Sept. 12, 1911. Vaginal examination: Vault of vagina is occupied by an indurated crater; uterus is enlarged to two fingers above the symphysis. As yet there is little extension into broad ligaments. Recto-vaginal septum is infiltrated with the growth, especially on both sides.

Discharged on request.

Patient seemed much improved in general condition and was relieved of pain.

Case 3. *Gynecological Records,* vol. 167, p. 269. N. W., aet. 55. Married; born in Ireland. Admitted to hospital July 24, 1911.

Previous History. Gyn. Records, vol. 166, p. 193. Diag. carcinoma uteri. Discharged on request. In hospital one week. Not relieved.

Readmitted July 24, 1911.

Obstetrical History. Full term, 0; premature, 4; last 20 years ago at 4 months; vaginal discharge, bloody; medium amount; red clots; continuous for five weeks; pulse, 92; temperature, 100°.

Aug. 19, 1911. Patient is having injections of cancerous ascitic fluid: complains of slightly less pain; temperature slightly elevated.

Aug. 16, 1911. 5 cc. of fluid injected into abdominal wall.

Aug. 19, 1911. 10 cc.

Aug. 22. 1911. 15 cc.

Aug. 23, 1911. Patient passed pieces of tissue by vagina, size of baseball; says she feels much relieved; injections continued.

Aug. 25, 1911. 15 cc.
Aug. 30, 1911. 15 cc
Sept. 2, 1911. 20 cc.
Sept. 6, 1911. 20 cc.

No temperature changes were noted referable to the injections.

Sept. 13, 1911. Patient died at 12 m.

Case 4. *Gynecological Records,* vol. 168, p. 221. C.D., aet. 50; single; born in Ireland. Admitted to hospital Aug. 18, 1911.

History. Patient has flowed almost continuously for nine months, and until two weeks ago. Pain across lower abdomen and in back for two weeks; none before. Has incontinence of urine and pain with micturition for three weeks. Vaginal discharge has never been foul. Has lost considerable weight and has had a cough for four to five months but raises nothing with it. Has often had night sweats.

Defecation, irregular; appetite, poor; bowels, constipated; digestion, poor; pulse, 90; temperature, 100.4°. Urine: alk, 1016; alb. s. t., few squamous and pus cells.

Physical Examination. Well developed but shows loss of weight; very anemic and looks 65 years old. Pulse is regular, of good quality slightly increased tension and not rapid.

Lungs: Negative except for sticky râles at both bases.

Heart: Normal size; systolic murmur over whole precordium and transmitted to axilla. A, P$_r$.

Abdomen: Soft and negative except for indefinite mass on left over sigmoid, apparently connected with the intestine; tenderness over whole lower abdomen on deep pressure.

Vaginal Examination. Stretched, intact introitus; good perineum; mucous membrane is pale; cervix is replaced by an indurated crater mass which fills the vaginal vaults with infiltrations extending on either side of broad ligament; uterus is not made out on account of abdominal rigidity; considerable brown, foul vaginal discharge; recto-vaginal wall also infiltrated; chain of glands in both groins.

Patient was given injections of cancerous ascitic fluid every third day in doses from 10 to 30 cc. from Aug. 20 to Nov. 17. Patient failed steadily and died on Nov. 22.

Case 5. *Gynecological Records,* vol. 169, p. 177. M. A., aet. 39; married. Nativity, Italy.

Sept. 12, 1911. Bleeding from vagina for a long time. Backache. Further history unobtainable.

Physical Examination. W. D. and emaciated. Patchy consolidations in the lungs. Abdominal: mass extending from pelvis three fingers, above symphysis. Vaginal: large ulceration involving entire circumference of upper vagina; cervix almost gone; marked induration throughout pelvis. General condition poor; cachectic. Inoperable carcinoma.

Course. In the hospital 25 days. Temperature irregularly elevated but tending toward the normal.

Sept. 16, 1911. 5 cc. ascitic fluid into abdominal wall. Temp. 99.8°—98.6°.

Oct. 3, 1911. 10 cc. ascitic fluid into abdominal wall. Temp. 98.6°. No reaction.

Oct. 8, 1911. Died suddenly, apparently of embolus.

Case 6. *Gynecological Records,* vol. 169, p, 181. M. B., aet. 55. A widow. Nativity, Boston.

Sept. 13, 1911. Pains; flowing; loss of weight for past 15 years (65 pounds). Menopause six years ago. No flowing till one month previous to entrance.

Physical Examination. W. D. and N. Heart; lungs; abdomen, negative. Vaginal: Cervix is cancerous; uterus is somewhat movable.

Sept. 14, 1911. Vagina not much infiltrated. G. C. poor. Rectal: Stricture of rectum, admitting tip of finger; infiltration of rectal wall. Broad ligaments quite free.

Course. In the hospital 33 days. Temperature irregularly elevated, maximum 102° Sept. 14.

Sept. 16, 1911. 5 cc. ascitic fluid into abdominal wall. Temperature 99°-100°.

Sept. 21, 1911. 7 cc. ascitic fluid into abdominal wall. Temperature 99°.

Sept. 25, 1911. 10 cc. ascitic fluid into abdominal wall. Temperature 99°-99.8°.

Oct. 1, 1911. 18 cc. ascitic fluid into abdominal wall. Temperature 98°-98.8°.

Oct. 5, 1911. 20 cc. ascitic fluid into abdominal wall. Temperature 98°.

Oct. 9, 1911. 25 cc. ascitic fluid into abdominal wall. Temperature 98° -99.2°

Oct. 14, 1911. 30 cc. ascitic fluid into abdominal wall. Temperature 98.4°-99°.

Oct. 16, 1911. Discharged with local condition unchanged, general condition much improved.

CONCLUSIONS.

1. These cases all showed a slight and irregular elevation of temperature, which, however, bore no apparent relation in its oscillations to

the injections of cancerous ascitic fluid, but seemed rather to be due to septic absorption from the ulcerating surface of the cancer.

2. The results obtained correspond with those obtained at the Massachusetts General Hospital. Cases 1, 4, and 5 gave no apparent reaction; Cases 2 and 6, according to their own statement, were relieved of pain and improved in general physical condition; the third case showed an apparent temporary relief of pain, and the tumor was apparently caused to slough, as evidenced by the tissue passed per vagina.

3. Four of the cases died of the disease and apparently without retardation. Two other cases were discharged and lost to observation.

4. That the injections of serum do have a beneficial effect can hardly be doubted, but whether this effect is due simply to a serum isotonic with the blood and acting as a stimulant or whether the reaction is specific, remains still to be proven. Patients with extensive cancer are usually cachectic and ill nourished, and therefore it is easy to conceive that the injection of a highly nutritive fluid, saline and isotonic with the blood, would have a stimulating effect and aid in the improvement of the general condition, and thus probably also the resistance to the inroads of the cancer. The reaction, however, is slight, very temporary and shows slight or no specificity.

Reports of Societies.

BOSTON SOCIETY OF PSYCHIATRY AND NEUROLOGY.

REGULAR MEETING AT THE BOSTON MEDICAL LIBRARY, NOV. 20, 1913, D. H. FULLER, M.D., SECRETARY.

DR. GEORGE A. WATERMAN read a paper on

THE RELATIONSHIP BETWEEN EPILEPSY AND MIGRAINE.*

DISCUSSION.

DR. G. S. DERBY: I was very much interested in one of the cases which Dr. Waterman reported, a man whose eyes I had an opportunity to examine. What struck me as most unusual was a permanent scotoma of the hemianopic type, which was present in the upper nasal quadrant of the left and in the upper temporal quadrant of the right eye. The outlines of the fields for white were normal. The colors were somewhat contracted, and showed a marked degree of interlacing. The fundus examination showed nerve-heads which were somewhat blurred and congested. Previously, I had not seen cases of this type, with a permanent scotoma, in connection with migraine or epilepsy, and it seemed to me that it must represent an organic change, probably brain tumor.

DR. P. C. KNAPP said that although Dr. Waterman had collected more evidence in favor of the relation between migraine and epilepsy than he had supposed could be found, he was nevertheless not convinced that the apparent association of the two affections was anything more than a coincidence. The treatises on nervous diseases thirty or forty years ago had much to say of the relation between the two affections; some of the more recent works, notably the new work edited by White and Jelliffe, do not even refer to it. As has already been said the convulsive seizure and the attack of migraine may at times be merely syndromes, due to some morbid process in the brain, and not independent diseases. Hence it is possible that a single underlying disease may produce at one time migraine, at another a convulsion, just as the cortical degeneration of general paralysis may produce an apoplectiform seizure or a convulsion. Although migraine is chiefly a sensory disorder, it may at times be preceded by a motor aura-aphasia or hemiplegia. A permanent hemianopsia or segment defect, due possibly to a hemorrhage, is occasionally seen. Dr. Thomas a few years ago reported several cases and he had seen several himself. Of all common affections of the nervous system, migraine is the one which most frequently shows a familial occurrence and is usually markedly hereditary; in epilepsy, on the contrary, similar heredity is rather rare and a pronounced familial occurrence is almost unknown. He had found migraine, in some large families, fifteen or twenty or more, affecting over fifty per cent. of those investigated, yet in no case was there any trace of epilepsy. Epileptics, of course, often have headaches, especially after a fit, and the headache may occur after an attack of petit mal or an attack in sleep, of which no note has been made. Headache, however, is of extremely common occurrence,—only 10 in 3000 cases investigated by Jelliffe being exempt, but not every headache can be regarded as migraine. Again, epilepsy is usually a progressive disease, often leading to dementia, whereas many cases of migraine recover after the age of fifty, and the disease never leads to mental deterioration. Although he had had the relation between the two affections constantly before his mind, as a result of early reading and the frequent discussions on the subject, he had failed to find in actual practice in the last thirty years any such association, and, above all, he believed that there was no justification for suggesting any such association to the epileptic and still less to the migraine patient.

DR. G. L. WALTON: We have listened to a masterly argument in favor of a case which has always seemed to me inherently weak. The material collected to substantiate this claim has a rather formidable aspect until we remember that the list comprises a comparatively insignificant number of isolated and unusual cases selected from an enormous mass of material consisting otherwise of typical migraine and epilepsy offering no suggestion of resemblance or analogy beyond the superficial one to which I shall shortly refer. Indeed, we are not sure that they are all cases of migraine and epilepsy, whether typical or atypical, and that cases have not been included in which unilateral headache and

*See page 387.

convulsion have arisen from other cause or causes than migraine and epilepsy. I remember very well a case of pituitary tumor in which unilateral sick headaches, with temporary hemianopsia, preceded, for many years, the permanent loss of visual field and the other diagnostic signs of the lesion from which the patient died, and which was confirmed by autopsy. I do not know today whether these early headaches were symptomatic of the tumor, or were migranous and merely a coincidence. Whatever the fact, neither this history nor a hundred such histories would lead the most speculative clinicist to argue a relation between migraine and brain tumor. Nor can I see that the line of reasoning by which it is attempted to draw an analogy between migraine and epilepsy is much sounder.

Again, in estimating the value of the statistics collected to fortify this claim we must not neglect to exercise the control without which such statistics are of no value. Thus, migraine is a very common, and epilepsy a fairly common disease. In looking up the subject of migraine, I found in one hundred healthy persons, seventeen typical cases of migraine, and more of migranous headache. It is not surprising, therefore, that a certain investigator has found forty cases of migraine among the children of some two hundred epileptics. We should expect not far short of forty cases of migraine among the children of two hundred healthy persons taken at random. If the children averaged more than one to an individual (a fact upon which we are not enlightened) we should not be surprised at an even greater proportion of migraine. If these statistics show anything, then, instead of fortifying the contention of the reader, they show that there is no more migraine among the children of epileptics than among the children of other individuals.

A word upon the so-called resemblance between these diseases. This resemblance seems to me a very superficial one, bearing little relation to the fundamental characteristics of the two conditions. The pathognomic features of epilepsy are (1) unconsciousness, (2) the brief duration of the convulsions which are supposed to be the motor analogue of the pain in migraine, (3) the fact that whatever movements are made or whatever psychic equivalents may appear are unconscious and automatic. In migraine, on the other hand, (1) there is no suggestion of unconsciousness, (2) the duration of the pain is one of hours instead of minutes, (3) there are no automatic and unconscious movements, and the psychic equivalent is a conscious one. The main resemblance seems to lie in the fact that both are recurrent with more or less periodicity, and that, in each, an aura is apt to precede the attack. But even when the visual aura, which commonly precedes migraine, precedes epilepsy, it generally is not characterized by scotomata, but is oftener irritative (hallucinatory) in its nature.

The practical question is whether we have enough evidence of the analogy and interchangeability of these diseases to warrant frightening the victim of migraine with the prospect of becoming an epileptic. I can only say that I am decidedly of the opinion that we have not.

DR. E. S. HODSKINS: I have seen only one case in which attacks of migraine were followed by typical seizures. This patient had severe attacks of migraine for several years until finally the migranous attacks would alternate with epileptic convulsions, which finally replaced the migranous attacks altogether. I have also seen one case in which epilepsy and migraine were combined and seemingly the two diseases had no relation to each other. Dr. Knapp has spoken of the small number of epileptics in which he has obtained a history of similar heredity, this has been my experience.

In closing the discussion DR. WATERMAN said: Some years ago Dr. Putnam published an article descriptive of the relationship existing between migrain and supraorbital neuralgia. On account of his well-known interest and wide experience in the diseases under discussion this evening I should like to read his opinion on the question in hand which he sent me together with a note saying he regretted his inability to be present.

"I have seen, as no doubt others have, a number of cases illustrating very strikingly the affirmative side of your proposition with regard to the connection between epilepsy and migraine. I suppose, on the other hand, that when it comes to the pathology of these disorders, no very definite work has been done in the way of establishing a close relationship. For my part I am a believer in the "neuropathic family idea of Féré and others, and I think that the two affections of which you speak do stand closer to each other than most of the others on the neuropathic list, although the difference in respect to relatedness is one mainly of degree.

"Dr. Clark and other men have written interestingly on the subject of myoclonic disorders, some forms of which also bear a close relationship to epilepsy, as no doubt you know.

"One more point has always seemed to me important—namely that I presume we all of us have, in a latent form, lying beneath the surface, as it were, the possibilities and potencies of many forms of inferiority (developmental, autotoxic, etc.) corresponding to all these types. In other words, our organisms are like crystals which one might assume to be capable of fracturing in various different planes but far more easily in certain planes than in others, and although with most of us these fractures may never actually occur, yet any one of them might occur under sufficient stress. There are, in short, I think, many points of less resistance, even in healthy persons, corresponding to the actual defects seen in persons in whom these 'fractures' actually take place. Speaking clinically and practically, I suppose few persons would maintain that migraine, which is so common, ought to be considered as a bar to marriage, while epilepsy should be so considered. What do you think on this point?"

In reply to Dr. Walton's objection to the points of similarity between the two diseases described in the introduction of the paper; I am willing to concede that in the sense of an explosion, meaning a sudden outburst, that an attack of migraine could not perhaps, be considered an explosive phenomenon. He must admit, however, that just as epilepsy is a liberation of motor energy, migraine on its part, represents a liberation of sensory energy. The fact that the aura, when visual, may have different qualities in the two diseases is of course generally known. Just as it is recognized that the character of the paraesthesia of the arm and face differ in the two diseases in the rapidity of onset and the areas involved. These are points of difference between the two diseases, although even here their borderlands may meet as in the occasional instances when the same type of aura may introduce at one time an at-

tack of migraine, and at another time an attack of epilepsy in the same individual.

In general we must recognize that the frequent occurrence of an aura in both diseases indicative of a disturbance in a definite cortical area, does suggest a similarity between the two diseases, as does also the fact that in both neuroses, this aura may occur at times independently of an attack.

That psychic equivalents are not seen in migraine as well as in epilepsy, is of course, not true. Many writers have described psychic symptoms in attacks of migraine, similar to those in patients suffering from epilepsy. Kovalevski has reported cases of migraine in the course of which typical "dämmerzustände" analogous to the epileptic form, made its appearance, and I would call attention to the observations of Zacher, Brackman, Mingzini, Féré and Krafft-Ebing who have described migraine attacks associated with psychoses, as hallucinations, stuporous conditions, impulsive movements and amnesia. Though these instances do not exhibit an absolute loss of consciousness, they do indicate similarity in the alteration of consciousness described.

The fact that Dr. Hodskins has seen three thousand cases of epilepsy and never noted any relationship to migraine in but one of them is interesting, but does not, of course, mean that such relationship may not have existed in some of them, if the cases had been studied, with such an investigation in view. I presume we have had two or three thousand cases of epilepsy at the Massachusetts Hospital in the past ten or fifteen years, yet I doubt if the records would anywhere mention that a relationship to migraine has been observed, and yet only three days ago, having this question in mind, I called back a girl, who was being treated for epilepsy, as she went out, and learned on inquiry that she had suffered from migraine until eighteen, when the attacks stopped and gave place to petit mal, which in turn, developed a few years later into major attacks. How many more such cases might have been found if careful inquiry had been made of other patients is, of course, conjecture. But these points of relationship must be brought out by questioning, they are not presented to one.

Dr. Knapp's contention that the question of relationship between epilepsy and migraine is an old and discarded one, is, I think, unfounded, for although early writers did recognize and discuss it, much attention is paid to it in many articles during the past ten years, several of which have been referred to in the foregoing paper.

While Binswanger, in his recent book on epilepsy gives two pages to it, Flateau in his excellent monograph on migraine, devotes at least ten or twelve pages to the discussion of the subject. The case Dr. Knapp refers to in which a patient with persistent hemianopsia died of a cerebral hemorrhage, does not, I think, have any bearing on the patient referred to in the present paper, in whom the attacks of sick headaches were replaced by headaches and epileptic seizures preceded by scotoma in a young person. Of course, instances of patients suffering from night attacks of epilepsy, waking with morning headache, have been observed by most of us who are familiar with the disease. I do not think, however, that this error would apply to any, but one of the cases reported in the foregoing paper; in Krafft Ebing's case it was recognized that hemicrania did follow, in the morning, the epileptic seizure of the preceding night.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

THIRTIETH ANNUAL MEETING HELD AT WASHINGTON, D.C., MAY 6, 7, 8, 1913.

(Continued from page 322)

DISCUSSION OF DR. PRATT'S AND DR. DALAND'S PAPERS.

DR. MINOR said: As regards the question of tension, Dr. Pratt's remarks on the therapeutic use of water interested me because we all have a number of cases of high tension in which, after a while, you exhaust all your therapeutic resources and you come up against a dead wall. You have tried the nitrites and the iodids, which I still firmly believe in, and dietetic regulation, and hygienic regulation, but when they fail us I believe that warm water will prove our most valuable resource.

Like Dr. Daland, I have not found very much use in nitroglycerine, and I am always looking for something which will meet the needs of these cases of hypertension. They are increasing in our country every day. Owing to the foolishness of our American system of living, they are taking larger toll of people, and we are getting more and more cases in which it is very essential for us to find some means of holding down that pressure. There are some agencies that are reported to have a wonderful effect, and they talk to us a great deal about high frequency currents, and it is unquestionably remarkable how such currents can temporarily greatly reduce blood-pressure, but I have never found anything permanent in their effects. The patient cannot constantly be running to take electricity, but everybody has at his disposition a tub of hot water. As to whether the addition of carbonic acid in the low tension cases is so valuable, I do not know, but in high tension cases I am a firm believer in hot water.

DR. PRATT: Dr. Minor suggested that I should use a greater variation in the temperature of the baths. My object was not the reduction or elevation of the blood-pressure, but the study of the action of the carbon dioxid baths on the blood-pressure at the temperature at which the baths are used in the treatment of heart disease. I have used the iodides in a large number of cases of hypertonia during the past ten years, and I have never been able to convince myself that they produce a fall in the blood-pressure. I do not believe you can reduce the blood pressure in chronic nephritis permanently by any measure, and if it could be done, I am not at all sure that it might not be harmful. Bier pointed out many years ago that the rise in blood-pressure in nephritis possibly was an aid to the functional power of the kidney. This method of treatment should be given a fair trial. I believe it is very important to make observations on the pulse and the effect of each bath on the blood-pressure. In every treatment that has been given I have always insisted that trained attendants should record the blood-pressure before and after the bath and, of course, the temperature and strength of the bath should be carefully recorded. It is said that you can lower the blood-pressure in chronic nephritis by dietetic regulation. In one of my cases of chronic interstitial nephritis, with a strong heart and hypertonia, the effect of a low protein diet was

carefully studied; the food was reduced in protein to less than 40 gms. a day, but at the end of the month there was no definite fall in his blood-pressure. Dr. Folin examined the blood in two of my cases of hypertonia without nephritis, and found that there was no abnormal increase of non-protein nitrogen in the blood. I find that I did not make clear the test that I proposed. Give the patient a bath of full strength at 90 degrees for ten minutes; a fall in the blood-pressure is the sign of a weak heart. Normally, a distinct rise in the blood-pressure results from this bath. If cool carbon dioxide baths 89° to 92° F. produce a fall of blood-pressure they will do harm rather than good.

Dr. Babcock: When you say the temperature is 90°, will you tell me the strength of your bath as to carbon dioxide?

Dr. Pratt: The total strength of the bath is prepared by adding 1000 c.c. hydrochloric acid, and 1000 gms. of sodium bicarbonate to a tub of ordinary size filled with water. Hydrochloric acid injures solid porcelain tubs, as well as those made of iron. The substitution of formic acid for hydrochloric acid, as recommended by Dr. Hinsdale, is a practical and useful improvement in technic.

Dr. Daland: I am not in accord with the view that hypertension is always compensatory. I believe it is always symptomatic, and occasionally compensatory. I agree very heartily with Dr. Elsner when he speaks about the wide distress in the minds of the patients on the announcement of the physician that he is suffering from hypertension, and also agree with him that the influences of sorrow and distress are a cause of this same condition. And I think this announcement of the condition will make him worse. Dr. Babcock dwells very properly upon the enormous influence of rest in these cases as a wonderful factor in many of these cases of high blood-pressure. As to the beneficial influence received by a patient from nitroglycerine in doses of 1-250 grains dry on the tongue, these beneficial results are perhaps to be accounted for on the ground of their psychic effect. Many of these individuals are generally thrown into a high state of nervous tension by the oncoming of an attack, and are directly greatly benefited by regarding this aspect of the case.

Dr. Frank Taylor Fulton, of Providence, R. I., read a paper on

AURICULAR FLUTTER

and reported a case. Auricular flutter is a term applied to a condition which is characterized by an extremely rapid action of the auricle, the rate being usually somewhere between 200 and 330 per minute. It is the result of some pathological impulse formation. The ventricular action may be varied. As a rule, there is always some grade of heart-block. Most commonly the ventricle rate is one-half that of the auricle; it may, however, be one-fourth that of the auricle, or the transmission of the impulse to the ventricle may be very irregular, so that the pulse may closely resemble the pulse of auricular fibrillation. Flutter is closely related to fibrillation, as well as to regular tachycardias of less rapid rate than itself. The condition has been considered to be rare, but the electro-cardiograph has demonstrated that it is probably not very uncommon. It may be detected by the use of the polygraph, although the tracings made by this means are sometimes extremely difficult to interpret. It is not necessarily a permanent condition; the heart action may return to normal and remain so for a long time. It sometimes occurs in paroxysms; the case in point is paroxysmal in type and has been under observation for seven years, during which he has had many attacks, the paroxysms at times lasting for ten or twelve hours or more, but more lately have been less severe and last only for an hour or two. The tracings show the radial and venous pulse during the paroxysm and at the time of transition to the normal rhythm.

Evidence seems to show that the origin of impulse is not from the normal point of origin; some other point than the normal pacemaker has taken on the function of stimulus production. The reasons for this were stated. The first case reported was in a man of 48 suffering with progressive, chronic nephritis with paroxysmal dyspnea and edema. Onset sudden while in the hospital. The flutter lasted for a month, and suddenly became normal. Digitalis in moderate doses of the tincture was given, but without effect. The rate was 143 per minute and there was Cheyne-Stokes' breathing. The patient is still in the hospital. The second case occurred in a man of 54 with gradually increasing edema and dyspnea for a year, due to chronic nephritis and an enlarged heart in decompensation. The pulse-rate was 136 to 138. The auricular waves in the venous tracing were at the rate of 272 per minute. The rate slowed after using digitalis, due to an increased grade of heart-block.

The third case was in a man of 70. There was palpitation following a nervous breakdown. Tracings of these cases were shown by lantern slides.

Dr. Fulton: I emphasize particularly the analysis of the radial curves because I am convinced that many cases with this mechanism can be diagnosticated without any mistake by the radial curves alone. There are other conditions which might bring about somewhat similar appearances, but I think there is no question but that the radial tracing alone is of a great deal of value in making the diagnosis; the reason that it is of value is that cases have been simultaneously studied with the electrocardiograph and the polygraph, so that the tracings which are so clear with the electrocardiograph can also be identified by the use of the other instrument. The possibility of extra-systole must, of course, be kept in mind.

Dr. F. Fremont-Smith, of Washington, read a paper on the

NUTRITIONAL EFFECTS OF INTERMITTENT ALBUMINURIA OF ADOLESCENCE.

Two brothers, aged five and nine, in 1901 developed an acute infection which was eruptive and was termed German measles by two competent physicians, but may have been scarlet fever. During their brief illness both showed albuminuria. It is not known whether they had albumen previously. For eight years both patients continued to present albumen from time to time, and at various hours during the day, with the utmost irregularity as to the hour. The cases were not orthostatic, postural or lordatic. The patients spent the winters each year in a balmy sub-tropical climate and the summers on the Maine coast. The striking fact was that the amount of albumen, the extraordinary irregularity of its occurrence,—one specimen loaded to an alarming extent, the very next absolutely free from serum albumen, regardless of the hour of the day, or of posture, continued un-

interrupted in the moist heat of southern winters or in the chill of the north. No nutritional faults were observed. The conclusion from studies of the literature corroborated the opinion that transitory albuminuria, intermittent or remittent, has little or no effect on the nutrition of the child, but that all such cases should be closely watched.

DR. GUY HINSDALE, of Hot Springs, Virginia, read a paper on

AMERICAN MINERAL WATERS: LATER ASPECTS OF THEIR ANALYSIS, CLASSIFICATION AND THERAPEUTIC PROPERTIES.

Dr. Hinsdale explained and illustrated the new form of stating water analyses, in which values are assigned to the various basic radicles and acid radicles and not to the familiar salts even in hypothetical combination. The latter method has been abandoned by U. S. Government chemists and all determinations are made in parts per million. The different groups of mineral waters and their therapeutic qualities were commented on. The subject of radioactive waters and their occurrence in the United States and in Europe was considered and also the means of artificially rendering a given water radioactive.. This involved the subject of radium and its emanation. The waters of the Yellowstone National Park and of the Hot Springs of Arkansas have been carefully studied and reported as radioactive by Government chemists. The electroscopic method was described and the various units of radioactivity were noted. The preference was given to the "Curie" or "Millicurie" used in France and in the United States. The author visited the water laboratory of the U. S. Department of Agriculture and reported that the chemists of the department were engaged in a study of all the available springs in the country.

DISCUSSION.

DR. A. JACOBI: I would like to know what the radioactive condition of all those wonderful mineral spas means for us. I am only a general practitioner and I want to know what they are good for. What do they claim the physical or theoretic effect is?

DR. W. E. CASSELBERRY, Chicago: I inquire if the author has formed an opinion as to the real efficacy of the radioactive qualities of the springs we mentioned. We have long ascribed the effects to the heat and elimination from the skin in the hot bath. It is well known that the hot springs of Arkansas have effects on certain diseases and that the chemical composition in these waters is almost identical with the composition of the waters of Lake Michigan, but it has been for years a mystery for which no explanation has been given as to what the superior efficacy might be due, aside from the heat and the elimination which seems an inadequate explanation, because the same effects could not be produced by artificially heating the water from Lake Michigan.

DR. KAHLO: This subject has been very extensively investigated in various parts of Europe. I have just returned from there, and took occasion while abroad to investigate this particular subject, and a great deal of importance is attached to this question there, not only at mineral water resorts, where the waters are more or less radioactive, but in the treatment of certain diseases by radium. A good deal of work has been done by Professor His in Berlin, and by Von Noorden and Falta in Vienna. They have used this treatment in a great many diseases, with varying results. I think that there can be no question as to the value of the radium treatment in certain forms of rheumatism and gout. How far these results differ when radium is used, and when the naturally radioactive waters are used, I do not know. They attach great importance to this treatment not only by inhalation, but hypodermically and by the mouth, and it is used very largely in the bath. There it is usually prescribed in the proportion in which radium emanation exists in the Gastein water. This is a subject which will receive more and more attention from the members of our profession in this country, because, while it is comparatively new, efforts are now being made to determine the exact degree of radioactivity of our own waters. The test by the fontactoscope is a very simple one. The technic is not difficult to acquire, and but little allowance need be made for the personal equation in such an investigation.

DR. FREMONT-SMITH, Washington: I beg to ask for information from Dr. Hinsdale whether there are any popular spas in Europe which are not radioactive. Also I should like to ask what is the grade of radio-activity of the springs of Hot Springs, Va.

DR. HINSDALE: Dr. Jacobi inquires about what value radioactivity would have for us in the treatment of disease. I have had no experience with treatment of patients by distinctly radioactive measures although the Germans have published a great deal about it, and the work of Klemperer is probably the most complete exposition of it. They all seem to claim great benefit in the treatment of rheumatism and gout and chronic affections of that type. We, I think, in this country have not received data enough to know what waters are radioactive. The government has not yet announced what waters of Virginia are radioactive. They have been tested by the government experts, and I suppose we will hear more about that later, but I am in no position yet to make any publication about it. There is a very long list of European spas that are found to be radioactive, graded according to measured scales. We will probably find that most all the springs of Europe are such. As far as the proportional assignment of benefit to the radioactivity and to other features of the spa treatment, I may say that at Aix they do not claim that radioactivity is the principal means by which benefit is derived. They attribute a great deal of benefit to the moisture and to the heat and to the manipulations which are given at Aix. Of course, they do assert that the radioactivity helps to some extent in the treatment of these cases. They are not dogmatic in their claims. I wish that I could give you more definite information about the radio-active springs of this country, but we are not in a position to make any definite statement about it, perhaps next year we may do so.

DR. ROBERT H. BABCOCK, of Chicago, read a paper on the

CAUSE OF BRONCHIAL ASTHMA.

He said that in every case of asthma one should search for some focus of chronic infection in the nasal accessory sinuses, in a chronic hyperplastic ethmoiditis, or in some closed cavity in any other part of the body. If found, advise its removal by surgical interference. If the absorption of a foreign protein can be presented in this manner, it is likely that the asthmatic seizures will be prevented or greatly ameliorated. In cases of asthma traceable to

animal or vegetable emanations or to some article of food to which the person has become sensitized, we can do nothing more than avoid exposure to the exciting cause. Dr. Babcock with other investigators concludes that bronchial asthma is a manifestation of anaphylaxis, or a protein sensitization or hypersensitiveness on the part of the animal to protein introduced into the system either by way of the alimentary canal or parenterally, *i.e.* some other channel which permits absorption.

DR. W. E. CASSELBERRY, Chicago, read a paper on

THE RECOGNITION OF EARLY CHANGES IN THE LARYNX IN TUBERCULOSIS.

The first definite change provoked by the bacillus in the larynx is an infiltration of the mucosa and submucosa, the tubercles being deposited near enough to the surface to change its aspect. The infiltrations fall into three groups:

1. Mammillated hyperplasia, by reason of the globular form of tubercles.

2. Granulomatous and verrucous formations, which may make an early appearance, although usually they appear only after ulceration.

3. Incipient edematous hyperplasia, rarely gross edema.

Favorite sites stamp upon the lesions additional distinctive marks, one of the most characteristic of which, a furrow in the vocal angle, has received little notice. Mammillated hyperplasia, commencing at the base of the vocal process and marked by a furrow in the vocal angle, is the most distinctive and one of the earliest signs. Interarytenoid hyperplasia, alone, is indistinguishable from non-tuberculous forms. But both together solve the problem of differentiating tuberculous laryngitis, from simple laryngitis in a tuberculous subject. This question concerns mostly the hopefully resistant type in which, if recognized early, the results of treatment justify every effort and any sacrifice. Somewhat later a bilateral development of the furrow in the vocal angle leads to an appearance or squaring of the semicircle of the posterior commissure, which is strikingly characteristic. Thus a diagnosis from the laryngeal image alone is usually, albeit not invariably, possible, every additional test being exceptionally required to remove all doubt.

DISCUSSION.

DR. C. L. MINOR: I am satisfied that too many neglect to examine the larynx of patients. Every man who has examined the lungs has not done so satisfactorily until he has also examined the nose and larynx.

DR. C. C. BROWNING: We have not completed the examination of the respiratory tract of a tuberculous patient until the nose and throat have been thoroughly examined. The larynx should be carefully watched, especially during the beginning of the use of tuberculin. Frequently changes will be brought about in the larynx before they would be noticeable in the lung, or by the temperature or other signs which we are likely to look for in the detection of tuberculosis, and if the dose is repeated too frequently or is too large we may bring about disastrous results in the larynx, when by the careful watching and graduating the doses by the condition of the larynx we may bring about an excellent result. I am satisfied that the universal recommendation, without further consideration, that you should put all patients out of doors and unprotected may have its exceptions. Not that the general principle does not hold good, but we must individualize in our cases.

DR. KINGHORN: I would like to ask Dr. Casselberry as to treatment. I have often been doubtful whether to put the patient's voice at absolute rest, suspecting a tuberculous condition, or whether simply a modified rest of the voice. I would like to ask whether he would put the patient at absolute rest.

DR. CASSELBERRY: You may have noticed that the effort in the paper has been to systematize the early lesions of tuberculosis of the larynx and to formulate a rule of thought as an aid to their recognition. The lesions are so diverse that I felt, unless one could reduce their presentation as well as recognition to order, that nothing would be gained. Examination of the larynx is rendered comparatively easy by a one per cent. cocaine solution sprayed sparingly into the fauces, not mopped on with cotton, and it is harmless if one tells them to spit out, and not to swallow immediately afterward. Furthermore, for those who are wearing glasses the substitution of an ordinary small, well-focussed brilliant head light, which eliminates one angle of reflection from the course of the light, has the advantage of disclosing small lesions in the larynx with less blurring of outline.

In regard to rest for the voice in the treatment. Yes, provided it be tuberculosis of the larynx and not merely laryngitis in a tuberculous subject, he should have perfect rest if he will take it. Absolute rest to the voice is one of the first principles of the treatment, but one must know that it is tuberculosis of the larynx before feeling justified in subjecting a patient to such a trial and inconvenience.

(To be continued.)

Book Reviews.

The Elements of Bandaging and the Treatment of Fractures and Dislocations. By WILLIAM RANKIN, M.A., M.B., Ch.B. With 68 original illustrations. London: Henry Frowde, and Hodder and Stoughton. 1913.

This small volume in the series of Oxford Medical Manuals is based on the author's demonstrations to medical students preparing for the practical portion of their final examination. One may well cavil with its opening statement that "the fine art of bandaging is no longer a necessity." Indeed, the section on bandaging, constituting one-fifth of the book, teaches little but the spiral reverse, figure of eight, and spica. The section on fractures, comprising three-fifths of the book, is equally meagre for so important a subject, though the essence of its teaching is excellent. The section on dislocations is correspondingly brief. The figures throughout are excellent. Despite certain merits, the book as a whole is one which for obvious reasons is not to be recommended. No doctor ought to undertake the treatment of fractures or dislocations who does not know more about them and about bandaging than is here set down.

THE BOSTON
Medical and Surgical Journal

THURSDAY, MARCH 5, 1914.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States. $6.56 per year for all foreign countries belonging to the Postal Union.*

Papers for publication, and all other communications for the Editorial Department, should be sent to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston. All orders for reprints must be sent in writing to the Editor on or before the day of publication.

The Journal will furnish 100 reprints free, if requested in writing.

All letters containing business communications, or referring to the publication, subscription or advertising department of the Journal, should be addressed to the undersigned

Remittances should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

THE INTERPRETATION AND MANAGEMENT OF LOW BLOOD-PRESSURE.

MEDICAL literature at the present time teems with references to high blood-pressure, its significance, and measures more or less efficient in causing its reduction. Of course we meet with numerous incidental allusions to low blood-pressure also; but it may safely be said that there is decidedly less definite information regarding it. One of the most illuminating contributions which has as yet been made to our knowledge of the subject, and one which is especially worthy of note as being based on practical observation and experience, is to be found in an address by Dr. Edward E. Cornwall of Brooklyn, N. Y., at the sixteenth annual meeting of the Associated Physicians of Long Island. The variations in blood-pressure found in different individuals, he very properly states, are so great, both in apparent health and in conditions of compensation of the circulation necessitated by disease, that it is impossible to draw rigid lines and say that pressure below these lines is abnormally low. Only such a general statement as the following can be made, and this must be subject to exceptions: For a young adult a systolic pressure of 100 mm. of mercury may be low; for a person of middle age, one of 110; for an elderly person, one of 120; for a person with sclerosis or spasm of arteries supplying a vital region, one of 140; for a person with advanced interstitial nephritis, one of 180. These, as mentioned, are systolic records, and such as are generally taken as the measure of the blood-pressure; but if our observations are confined to the systolic record alone, their clinical value will be small, and we will frequently find the inferences drawn from them contradicted by other evidence. The diastolic pressure is fully as important as the systolic, and the author therefore considers it essential to consider the records of the two together in their numerical relations, that is, the difference between them and their place in the pressure scale; which affords a very useful, though only partial, index of the degree of efficiency of the circulation. The difference between the systolic and diastolic pressure tells us the fall in the circulation between the heart and the arterioles, and is analogous to what in hydrostatics is termed a "head of water." This fall is the pulse-pressure. There is reason to suppose that there is a particular place in the pressure scale for each individual and each particular condition where a given pulse-pressure, other things being equal, will produce the fullest circulation, and one at the same time attended with the greatest circulatory flexibility and reserve power; also that pulse pressures placed above or below this ideal point in the scale, in order to produce an adequate circulation, must ordinarily increase in magnitude, that is, take on an overload, and that such an overload means more or less diminution in the flexibility of the circulation and in the reserve power of the heart. If the diastolic pressure fails to fall in correspondence with a falling systolic pressure, thereby permitting the pulse-pressure to become unduly small, or if, on the other hand, the diastolic pressure falls so low, relatively, that the pulse-pressure takes on a large overload, clinical symptoms of circulatory insufficiency may appear.

Low blood-pressure, although frequently pointing to myocardial degeneration, Cornwall believes more often signifies vasomotor relaxation or paralysis due to toxemias or to nervous and reflex conditions. In uncomplicated cases of myocardial degeneration an extra demand on the circulation may increase the pulse-pressure disproportionately, and the failure of the systolic pressure to rise sufficiently to enable the pulse-pressure to assume the requisite overload may be a measure of the extent of the degeneration. In cases of such degeneration accompanied by arteriosclerosis or nephritis, which naturally raise the diastolic pressure, there is regularly an increase of the systolic pressure,

and an overload in the pulse-pressure, so long as the reserve power of the heart holds out; but when this power, already encroached upon by the myocardial degeneration, is no longer sufficient to support the overload, the circulation fails with the falling systolic pressure. In instances of myocardial degeneration with coexisting conditions which require a compensatory high pressure, the appearance of low blood-pressure is to be looked upon as a bad prognostic sign. Very many chronic toxemias of intestinal origin, as is well known, are associated with conditions which produce high blood-pressure, such as arteriosclerosis and nephritis, but many others are attended with low pressure. In the latter class of cases a nonputrefactive diet is found to raise the pressure, while in the former a diet of this character constitutes a most valuable means of lowering the high blood-pressure. In most acute infections the systolic pressure is low, and the diastolic also, unless there is an obstruction in the periphery. In lobar pneumonia, however, lowering of the blood-pressure to any considerable degree occurs less commonly than in most acute infectious diseases. Ordinarily it is lowered somewhat at the onset, and again at the crisis. In cases of apparent primary vasomotor paralysis and in cases with pronounced myocardial failure, which are not uncommon, the blood-pressure is likely to be very low. In 27 out of 30 cases of pneumonia, all of which terminated favorably, the systolic pressure fell below the pulse-rate; thus contradicting the assertion of Gibson and Hare, that when this occurrence is noted in pneumonia, the prognosis is bad. In pericarditis, as in myocarditis, there is regularly diminution of the systolic force and a lowered systolic pressure, while in compensated valvular disease the blood-pressure is usually normal, except in the case of aortic incompetence, where the systolic pressure is regularly high and the diastolic regularly low. When there is pronounced loss of compensation in valvular disease the blood-pressure falls. In chronic wasting diseases generally the pressure is low, and the same has been observed in cases of excessive tobacco smoking. Surgical shock is recognized as an effective cause of low blood-pressure.

The diastolic pressure appears to be more stable than the systolic, and to show less often marked variations from its normal without definite pathological cause. It indicates the peripheral resistance, which in many instances is determined by permanent pathological conditions. Vasodilator drugs may improve the circulation by increasing the pulse-pressure, while cardiac-depressant drugs may lower the diastolic pressure by diminishing the systolic force and calling for a pulse-pressure overload. In the interpretation of blood-pressure findings, considerable allowance may have to be made for the neurotic factor in the patient and the personal factor in the observer, and the clinician must constantly guard against being misled by these findings, and especially against ascribing too much importance to them when unsupported by other evidences of disease. In the treatment of low blood-pressure removal of the cause, if possible, is, of course, the first duty. If the cause is a chronic toxemia, it can very often be removed or lessened, and this is particularly true of intestinal toxemias. An essential element in the treatment of low pressure is rest, and in persistent low pressure following any of the acute infections, prolonged rest in bed is necessary. If there are definite signs of circulatory insufficiency, cardiac stimulants may be called for, and of the drugs of this class Cornwall has found strychnine, stropanthus and caffeine most generally useful. Digitalis, which may prove of great service in cases with low diastolic pressure and a fairly healthy myocardium, is contraindicated in those with myocardial degeneration and a relatively high diastolic pressure. In cases with sudden severe falling of the diastolic pressure due to toxemic vasomotor dilatation, adrenalin and pituitrin would seem suitable agents to employ. When there is low blood-pressure as the result of severe hemorrhage, the rapid introduction into the circulation of normal saline solution, as well as elevation of the lower part of the body, is called for. In some cases with a relatively high diastolic pressure and a small pulse-pressure, nitroglycerin may prove useful by enlarging the latter, but in cases in which the diastolic pressure is low this drug is absolutely contraindicated.

MEDICAL LEGISLATION. THE REGISTRATION OF NURSES.

THERE is at present pending before the Massachusetts General Court a House bill (No. 1186) relative to the registration of nurses in

this Commonwealth. This bill provides for an amendment of the act of 1910 by substituting for one of its sections a new section as follows:—

"Applicants for registration under this section, who shall furnish the board with satisfactory proof that they are twenty-one years of age or over, of good moral character, and that they have received a certificate of graduation from a training school for nurses, giving at least two years' training in a hospital, and considered efficient by the board, shall, upon payment of a fee of five dollars, be examined and if found qualified, shall be registered and authorized to use the title 'registered nurse' and shall receive a certificate thereof from the board signed by its chairman and secretary.

"An applicant who fails to pass an examination satisfactory to the board, and is therefore refused registration, shall be entitled, within one year after such refusal, to a re-examination at a meeting of the board, called for the examination of applicants, without the payment of an additional fee. The said board may, after a hearing, by vote of a majority of its members, annul the registration and cancel the certificate of any nurse; and, without any hearing, may annul the registration and cancel the certificate of a nurse who has been found guilty of a crime or misdemeanor.

"The board shall have authority under this section to investigate at any time the training schools for nurses in this Commonwealth for the purpose of determining their fitness and efficiency, as shown by their general equipment, by the character, the methods, and the extent of instruction given therein.

"For the purpose of such investigation, the board may employ a person legally entitled to 'R. N.,' and who is a graduate of a training school for nurses connected with a hospital of at least fifty beds, and which gives a course of instruction in the art of nursing, covering a period of not less than two years."

The essential purpose of this amendment is to give the Board of Registration of Nurses authority to inspect the training-schools whose graduates, by virtue of their diploma, seek registration by the board. A previous attempt to secure legislation to this effect was made by the Massachusetts State Nurses' Association in 1913; but the measure then introduced was defeated in committee by opponents who objected that it would place too much power in the hands of the board. As a matter of fact, it does not seem that this argument is of importance, since the board is an appointive body from which one member is retired each year, and its personnel could readily be changed, if it showed any tendency to arbitrary abuse of authority.

The need and desirability of such inspection are obvious, for without it there can be no standard of training on the adequate basis of which a diploma may be accepted as evidence of fitness. The proponents of the bill have pertinently pointed out that similar training-school inspection has proved of value and success in New York and Illinois, where it has already been adopted. Such examples are important arguments in its favor.

The public needs protection against incompetent nurses as well as against incompetent physicians. The establishment of nurses' registration was a recognition of this fact. But that protection is not adequate without some means of assuring the quality of training received by the nurse who is a candidate for registration. This assurance is provided by the present amendment, and the inspection thus established would not only protect the public against the graduates of inferior schools, but would inevitably raise and make uniform the standards of nurses' training throughout the state.

The hearing for this bill is to be at the State House on Tuesday, March 10, before the Committee on Public Health. It is to be hoped that physicians who recognize its importance, and who are themselves vitally concerned in the maintenance of reliable training for nurses, will be present to speak in explanation of the bill and to advocate its favorable report and passage.

MEDICAL LEGISLATION. THE TUBERCULOSIS PROBLEM.

ON Tuesday of next week, March 10, at 10.30 a.m., there will come up for hearing at the State House before the Committee on Public Health the legislative bills introduced by the Recess Committee on Tuberculosis. These bills, embodying the recommendations of the full committee, include those from House 922 to 931 inclusive. At the same time hearing will be given to certain other bills, House 530 to 533, which have been introduced by a minority of one of the committee. In addition to these, House Bill 1828, not introduced by the Recess Committee on Tuberculosis, will also be heard. These latter bills, House 530-533 and 1828, which include a plan for the reorganization of the State Board of Health on the basis of a paid board of five members, the establishment of a

commission on tuberculosis, and the establishment of a definite policy for the treatment of tuberculosis, we believe to be unnecessary and unwise.

The policy of this JOURNAL in regard to the proposed reorganization of the State Board of Health has already been clearly stated. We are therefore opposed to any proposed legislation which departs from this policy. We are also opposed to any bills which will in any way hamper the centralization of authority in tuberculosis work, which is so desirable and which is strongly advocated by the Recess Committee.

The bills advocated by the full Recess Committee, House Bills 922-931, seem on the whole commendable and deserving of passage.

House 922, An Act to Establish a Department of Diseases Dangerous to the Public Health, is a commendable bill but unnecessary, as the State Board of Health, we believe, already has the power to establish such a department.

House 923, An Act Relative to Inspection by the State Board of Health of all Institutions Caring for Diseases Dangerous to Public Health; and House 924, An Act Relative to Supervision of Local Boards of Health by the State Board of Health, we believe to be wise and desirable.

House 925, An Act to Provide for the Care and Treatment of Incorrigible Tuberculous Patients in a Separate Institution, we believe should not be passed at the present time. The principle embodied in this bill is a commendable one, but further investigation should be made as to the advisability of caring for such incorrigible patients in an institution or institutions already existing, before the state is called upon to build a new and separate hospital for such patients.

House 926, An Act Which Allows Towns and Cities to Incur Indebtedness Outside Their Debt Limit for the Purpose of Building Hospitals, will help certain cities and towns to build local tuberculosis hospitals, which at present they are finding it difficult to do.

House 927, An Act to Allow the State Board of Health to Standardize Tuberculosis Dispensaries, is an excellent one and should by all means be passed.

House 928 defines the powers and duties of the State Board of Health in regard to the ventilation of school buildings in the Commonwealth.

House 929 repeals an existing law, that no hospital shall be established within 100 rods of an inhabited dwelling house in any adjoining city or town without the consent of such city or town. The bill is worthy of passage subject to the supervision of the State Board of Health.

House 930 is an Act Requiring the Trustees of Hospitals for Consumptives to Reserve the Westfield State Sanatorium for Women and Children Only. We believe that this question should be left to this board of trustees to decide.

House 931, An Act Relative to the Removal of Certain Persons Infected with Tuberculosis, will be of great assistance to local boards of health throughout the Commonwealth in caring for that most dangerous class,—the alcoholic and incorrigible advanced consumptive.

These bills, 922-931 inclusive, which have been briefly commented on above, represent the result of a summer of very hard work by the Recess Committee on Tuberculosis of the House of Representatives after about 40 public hearings. They bear on important phases of the health problem in this state, and should receive serious consideration and advocacy by the medical profession as well as by the legislature.

JULES CLARATIE AND THE MEDICAL PROFESSION.

BY the recent death of this great French author and journalist, the medical profession has lost one of its warm admirers and faithful portrayers in fiction.

One of the just criticisms of many modern novelists that the physician is entitled to make, is of the great liberties taken with medical facts and the ignorance displayed, almost childish at times, in dealing with medical subjects. Too much realism and practical medicine in fiction is surely to be deprecated by none more than the physician. Such statements as are made concerning well-known medical facts should, however, be accurate as far as possible for the day and generation in which they were made.

It is refreshing then to think of this great writer, a good friend of medicine, and of his works of fiction concerned with medicine. Among these, "Jean Mornas," and the "Amours d'un Interne" are perhaps the most notable. In the latter novel, according to an article in *La Chronique Médicale*, is shown a

profound knowledge of things medical and scientific. Claratie writes of hysteria especially in a manner showing deep knowledge of this subject. Many of the most unusual cases of this interesting and many-sided affection, he had the opportunity of observing at la Salpêtrière. The sick themselves, the internes, the wards and laboratories of hospitals were all described with wonderful accuracy, but not with pedantry.

When the tired physician seeks relaxation in the form of a novel, and literally has his teeth set on edge by some bizarre or impossible statement concerning medical matters, he will certainly long for the accuracy and care used by this great author in all subjects pertaining to medicine.

SCHOOL DENTAL CLINICS.

THE recently published proceedings of the meeting of the International Dental Federation at The Hague in 1913, show that there are in Germany over 200 school dental clinics; in Sweden, 40; in Norway, 10. Dr. Jessen, of Strassburg, chairman of the congress, announced the following outline of rules of dental care and conservative early treatment.

"From the age of two and one-half years it is desirable that children's teeth be inspected every six months in order to treat the deciduous teeth before they ache, and allow the children to enter the public schools with healthy mouths. It is desirable that every child from this age have his own toothbrush and be practised in its use. The mouths of children who come at an older age to the school clinics should be treated as much as possible in a conservative way. Decayed teeth which cannot be filled must be extracted. Dry roots of deciduous teeth must be left in the mouth till the permanent teeth appear. This will preserve the shape of the jaw. Decayed crowns with dry roots should be cut off and the roots filed smooth. The six-year molars are to be saved if possible until the age of twelve and must be extracted only when they cannot longer be saved or when there is not sufficient room in the mouth. Each child is to be treated individually with methods suited to his age, constitution and character."

ALPHONSE BERTILLON.

ALPHONSE BERTILLON, who did most to elaborate the science of anthropometry, from which he evolved in 1879 a system of criminal identification, died February 13, last. By his work the records of municipal police departments were improved far beyond those of their courts. The police of great cities now regularly exchange the Bertillon measurements of convicted men, and can thus recognize criminals of national and oftentimes of international disrepute. Bertillon was himself for thirty years the head of the Paris Bureau of Identification.

This remarkable man has been considered the inventor of the finger print method of identification, but erroneously. When Mr. William A. Pinkerton was in China he found that the merchants impress their thumbs rather than write their signatures on documents and business agreements, and have ever with them for this purpose a cake of ink. And this, it seems, has been the custom for centuries, from time immemorial, indeed. From China the use of the thumb print spread to India, whence the English introduced it to London. Francis Galton published his *Finger Prints* in 1892 and soon after his *Index of Finger Prints*. He computed that the chance of a finger print of an individual being duplicated by that of another is one in sixty-four billions. And he first reduced finger printing to a system and proposed it to Bertillon. The latter was for a long time skeptical as to its utility, preferring his own system of measurements. It is now a part of the Bertillon system. It was one of the most pitiful incidents of the Dreyfus trial that Bertillon, who had written several works on identification through handwriting, gave an expert opinion which went far toward sending the unfortunate soldier to Devil's Island. The question of the treason of Dreyfus hinged on the identification of letters written by him with that of the infamous bordereau. Bertillon concluded this document and these letters to have been written by the one person. And he so testified, as one of three experts engaged by the state, two of whom declared against Dreyfus, the third maintaining that the soldier had had nothing to do with the bordereau. With the latter two experts engaged by the defense coincided. The verdict at that trial doomed Dreyfus to imprisonment for life in the pestilential tropics. Five years after, through the efforts of Zola, Picquart and others he was returned to Paris, where his case was reversed in the manner with which all the world is now familiar.

MEDICAL NOTES.

LEGALITY OF VASECTOMY.—Report from Fort Madison, Iowa, on Feb. 19, states that a test case is to be made in the instance of a prisoner in the local penitentiary who protests against the operation of vasectomy which was to have been performed on him under the new law for the sterilization of criminals and insane. The convict will take legal procedure to resist its performance, and his fellow-prisoners are said to have raised from their earnings a sufficient sum to defray the costs of the trial. Despite one's realization of the undesirability of procreation among the unfit, one cannot help sympathizing with the attitude of the convicts.

SCARLET-FEVER AT UNIVERSITY OF ILLINOIS.—Report from Champaign, Ill., on Feb. 19 states that scarlet-fever is epidemic among students at the University of Illinois. There have already been a number of cases and two deaths of the disease.

ERADICATION OF MALARIA AND TYPHOID.—On Feb. 21, Senator Ransdell introduced into the national Senate a bill carrying an appropriation of $500,000 for the study and eradication of malaria and typhoid fever in the United States.

BOSTON AND NEW ENGLAND.

BIRTH OF TRIPLETS.—Report from Chatham, Mass., on Feb. 20, announces the birth to Mrs. Edward L. Clark, of that town, of triplets, two boys and a girl, weighing respectively 6, 6¼, and 7 pounds.

SALE OF MORPHIA ON TELEPHONE ORDER.—In the Boston municipal court on Feb. 20, Judge Murray ruled that it is illegal to sell cocaine, morphine, or opium, on an order given by a physician over the telephone, and fined a drug clerk $25 for so doing. The statute reads "upon the written prescription or order of a physician," and does not include on oral order given directly or telephoned.

HOSPITAL BEQUESTS.—The will of the late Mrs. William A. Abbe, of New Bedford, Mass., which was filed in that city on Feb. 21, contains a bequest of $50,000 to the St. Luke's Hospital of New Bedford, and one of $5000 to the Boston Lying-in Hospital.

NEW YORK.

SMALLPOX AND VACCINATION.—Health Commissioner Biggs recently addressed a letter to the health officers of the state in reference to smallpox. During the year 1913, he says, there were 823 cases of the disease in New York state. In the large cities of New York, Buffalo and Rochester, with a population of over 6,000,000, where the law compelling the exclusion of unvaccinated children from school has been rigidly enforced, there have been only 39 cases—mostly imported. Smallpox now exists in epidemic form in Niagara Falls, where there is a widespread sentiment against vaccination. The cases in this epidemic have been of a mild type, but in unvaccinated communities there is every possibility of the epidemic becoming far more serious. From Jan. 1 to Jan. 27 there were reported 154 cases at Niagara Falls and 15 cases at other places in Niagara County; also a number of cases in Chautauqua, Erie, Herkimer and Montgomery counties.

TWO NEW APPOINTMENTS. — Commissioner Biggs has appointed Dr. H. L. K. Shaw of Albany director of the division of child hygiene in the State Health Department. Dr. Shaw has been clinical professor of diseases of children in the Albany Medical College, and is at present chairman of the pediatrics section of the American Association for the Study of Infant Mortality. Commissioner Biggs has also appointed Dr. Augustus B. Baldwin of New York director of the division of laboratories and research. Dr. Baldwin is a graduate of the Massachusetts Institute of Technology and of the medical department of Columbia University. At the latter school he has held a number of positions, and from 1909 to 1913 was adjunct professor of bacteriology.

OUTBREAKS OF TYPHOID.—The State Health Department reports recent outbreaks of typhoid fever at Ellicottville, Cattaraugus County; Walden, Orange County; and Fishkill, Duchess County. The outbreak at Fishkill, it states, is a striking illustration of the quick spread of infection from one unsuspected source. An unrecognized case of typhoid, the infection of a few bottles of milk, resulting in four cases, the infection of a well by one of these cases, and then eight cases among the few persons who used the water of this well, giving a probable

total, exclusive of the first case, of 18 in a village of 500 inhabitants—all present a striking chain of evidence which would seem to leave no doubt as to the origin and development of this outbreak.

A CENTENARIAN.—Theodore Harris of Camden, N. J., died on February 13, at the alleged age of 110 years. He was a native of Maryland and served in the navy throughout the Civil War, and the records of the Navy Department appear to support the correctness of his great age, as they give the date of his birth as May 20, 1813.

ORTHOPEDIC DISPENSARY AND HOSPITAL.—The recently published forty-sixth year book of the New York Orthopedic Dispensary and Hospital, records the work of that institution for the calendar year 1913. During this period 7490 patients were treated at the dispensary, of whom 2506 were new cases. At the hospital, 510 operations were performed on 444 patients. The patients made 30,366 visits to the dispensary, and 11,022 visits were made by nurses to patients in their homes. A year ago an appeal was made to the public for $1,000,000 to erect, equip, and maintain a new hospital building. Of this sum, $545,000 have already been raised. A site has been selected and purchased, plans are in preparation, and the work of construction will be begun as soon as the remainder of the sum can be secured.

COST OF CARE OF ALIENS.—A report of the hospital investigating board, submitted on Feb. 19 to the New York board of estimate, states that the city expends annually $1,000,000 for the hospital and almshouse care of aliens, many of whom have entered this country within five years, and were diseased on admission.

OFFICERS, NEW YORK NEUROLOGICAL SOCIETY.—At the last regular meeting of the New York Neurological Society, the following officers were elected.

President, Dr. Smith Ely Jelliffe; first vice-president, Dr. E. G. Zabriskie; second vice-president, Dr. F. Kennedy; corresponding secretary, Dr. J. Ramsay Hunt; recording secretary and treasurer, Dr. C. E. Atwood; councillors, Drs. L. P. Clark, A. S. Taylor, F. Tilney, C. L. Dana, and I. Abrahamson.

4. Berlin invites discussion and investigation of some new ideas on the causation of Bright's disease. Nephritis, he says, is always of bacterial origin, and cultures taken from fresh urine will give abundant colonies of micro-organisms. The toxemias do not cause nephritis, although they do increase the blood-pressure. When acute inflammation of the kidney subsides it leaves the renal tissue damaged and degenerative changes, *i.e.* chronic nephritis, begin at once. [L. D. C.]

1. Mayo finds that such injuries practically never occur except as the result of a binding down of the duodenum from infection or carcinoma, or when the pedicle of the kidney slips and large forceps are applied and left on several days to control hemorrhage.

2. McWilliams concludes from experimental work that the theory that contact with living bone is necessary for the subsequent life of grafts must be given up. Living bone grafts have life inherent in themselves and are capable of permanent growth, even when transplanted into the soft parts.

The life of grafts is dependent on sufficient blood supply. Forty-eight per cent. of the author's bone grafts were successful without periosteum whether contacted with living bone or not. This goes to show that there is some other factor present making for the life of grafts than the periosteum or contact with living bone, and this the author believes is a sufficient blood supply. Periosteum, however, is a strong factor in producing this supply and should always be used when possible. [E. H. R.]

2. Gordon again enthusiastically endorses the cardiac sign in cancer and describes cases in which this sign has been of great help in diagnosis. This sign is based on the abnormal increase in the area of cardiac dullness. It is very hard to see why such increase should occur in loss of flesh due to cancer more than it does in other cases where the loss is due to other causes. [J. B. H.]

Obituary.

HORACE EUGENE MARION, M.D.

DR. HORACE EUGENE MARION, of Brighton, who died suddenly of heart disease on Feb. 8, was born at Burlington, Vt., on Aug. 3, 1843. In 1862 he entered Amherst College, but left to enlist in the Union Army, where he served in the ranks for the remainder of the Civil War. In 1866 he received the degree of B.S. from Dartmouth College, and that of M.D. in 1869. He immediately settled at Brighton, where he continued active in the practise of medicine until his death.

Dr. Marion was formerly president of the Middlesex South District Medical Society and was a member of the American Medical Association, the Massachusetts Medical Society, Massachusetts Association of Boards of Health, Boston Society of the Medical Sciences, Obstetrical Society of Boston and the Boston Medical Library Association. After the War he continued to serve in the local militia, and became medical director of the second brigade, M.V.M. He is survived by his widow, one daughter, and one son.

The unvarying cheerfulness of Dr. Marion's disposition made him, as a practitioner, particularly beloved by all his patients and colleagues. He was modest but vivacious, energetic and companionable. One of his many friends has fitly said of him that he went about with "high thoughts seated in a heart of courtesy." He died happily, as every physician would wish to do, without warning in the readiness of his daily activity, and gave his life as quietly at the end as he had always given it for his fellow-men.

Miscellany.

CHANGES IN THE MEDICAL CORPS, U. S. NAVY, WEEK ENDING FEBRUARY 21, 1914.

February 13, Medical Inspector William C. Braisted, detached from duty as Fleet Surgeon of Atlantic Fleet, and ordered to duty as Chief of Bureau of Medicine and Surgery, Navy Department, Washington, D. C.

Assist. Surgeon J. B. Walker, commissioned assistant surgeon in Medical Reserve Corps, from January 23, 1914.

February 18, Medical Inspector E. P. Stone, ordered to treatment at the Naval Hospital, New York, N. Y.

P. A. Surgeon W. L. Mann, Jr., detached from Naval Hospital, Mare Island, Cal., and ordered to Asiatic Station, via Army Transport leaving San Francisco, Cal., March 5, 1914.

Assist. Surgeon W. W. Wickersham, Medical Reserve Corps, ordered to Navy Yard, Brooklyn, N. Y.

RECENT DEATHS.

DR. FREDERICK H. OSGOOD, who died last week at Allston, Mass., was born in Newton, Mass., on April 16, 1857. He graduated from the Massachusetts Agricultural College in 1878, and after studying at the Royal Veterinary College, Edinburgh, settled in the practise of his profession at Springfield, Mass. He was for a time lecturer on cattle pathology and professor of veterinary surgery at the Harvard Veterinary Medical School. From 1884 to '87 he was president of the Massachusetts Veterinary Association, and served on its executive committee from 1888 to 96. From 1885 to 96 he was vice-president of the United States Veterinary Medical Association, and in the latter year its president. In 1891 he became veterinary surgeon to the Massachusetts Volunteer Militia. From 1894 to 96 he was chairman of the Massachusetts Cattle Commission. He was also president of the Association of Cattle Commissions of New England and a fellow of the Edinburgh Veterinary Medical Association. He is survived by a daughter and two sons.

DR. WESLEY B. PERKINS, who died on Feb. 19, at Roxbury, Mass., was born at Windsor, Me., in 1842. He was educated at Kent's Hill Academy, Me., and at Bates College, and practised as a physician at Bridgton and at Malden, Mass., until his retirement in 1906. He is survived by a niece and by one brother.

DR. JAMES A. COX of New York died on February 3, at the age of 55 years. He was a native of Kentucky and was graduated from the Long Island College Hospital in 1891.

DR. EDWARD GARDINER DAY of New York, a graduate of the College of Physicians and Surgeons in 1888, died on February 3. He was born in 1843 and retired from active practice in 1908.

DR. NATHAN S. MARSHALL, who died recently at Knoxville, Tenn., was born in 1831. He was a naval surgeon, and served aboard the *Vandalia* in 1854 under Commodore Perry.

DR. JAMES JOSEPH BURNS, of the Borough of the Bronx, New York City, died on Feb. 19, at St. Francis' Hospital, after an operation for appendicitis. He was born in New York, and was 33 years of age. Dr. Burns was graduated from New York University and Bellevue Hospital Medical College in 1902, and afterwards served as interne in Bellevue Hospital.

NOTICE.

THE BOSTON SOCIETY OF MEDICAL SCIENCES.—The next meeting will be held on Tuesday evening, March 10, 1914, in the Surgical Amphitheatre of the Boston City Hospital, at 8.15 o'clock.

The meeting will be conducted by the staff of the Boston City Hospital.

The program will be as follows:

Exhibition of cases.

Dr. F. W. White: "Benzol Treatment of a Case of Leukemia." (5 minutes.)

Dr. F. B. Lund: "Treatment of Oblique and Comminuted Fractures of the Femur." (5 minutes.)

Dr. Ernest Young: "Extra-Uterine Pregnancy." (10 minutes.)

Dr. F. J. Cotton: "The Principles in the Treatment of Infected Joints." (5 minutes.)

Dr. J. H. Cunningham, Jr.: "Specimen of Carcinoma of the Prostate, Associated with a Large Prostatic Cyst." (5 minutes.)

Dr. F. H. Lahey: "Statistics of 100 Deaths Following Appendicitis." (10 minutes.)

Dr. G. P. Sanborn: "Remarks in Intra-Spinous Serum Treatment of Syphilis of the Central Nervous System." (5 minutes.)

Dr. F. S. Graves: "A Case of Two Primary Heterogeneous Malignant Tumors with Metastases from Each in the Liver." (5 minutes.)

Dr. O. J. Hermann: "Observations on the Luetin Test." (By invitation.) (5 minutes.)

Dr. Horner: "Treatment of Typhoid Fever with Vaccines." (5 minutes.)

THOMAS ORDWAY, *Secretary and Treasurer*,
Harvard Medical School.

Original Articles.

VACCINATION EFFICIENTLY PERFORMED.*

BY EDMOND F. CODY, M.D., NEW BEDFORD, MASS.

City Physician, New Bedford, Mass.

One hundred fifteen years ago, Dr. Edward Jenner published "An Inquiry into the Variolae Vaccinae," and showed that vaccinal inoculation protected the human organism against smallpox. Subsequent experience has substantiated his observation, and variola no longer prevails in countries where vaccination is regularly and efficiently performed.

Where this important sanitary measure is irregularly practiced, as in the United States, the disease recurs at intervals, less severe than in former times, but nevertheless, with considerable mortality and at large cost to the community; as examples, in 1900, the cost of municipal control of 171 cases of smallpox to the city of New Bedford was $23,000; in the spring of this present year, a few cases in our city cost about $10,000.

Smallpox has prevailed in this part of Bristol County nearly every year since 1900, limited almost entirely to people who have come from that part of Canada called Arcadia, and who are without exception, unvaccinated. As their route of entrance is by rail they are not subject to the measures imposed at points of entry along the coast. Their children attend parochial schools and are not amenable to our statutory vaccinal requirement. The exceptions have been persons whose protection had long since run out.

The progress of preventing smallpox in a country like ours where vaccination is optional after the age of entrance to public schools, is rendered difficult by persons who would have others believe that the procedure is useless, harmful or fatal. Organized opposition to vaccination appears to have had its inception in Jenner's England, where compulsory vaccination may now be evaded by a declaration of conscience. An English gentleman could offer no other explanation for this opposition than the well known love of the English to protest against law. Physicians, unburdened by knowledge and unrestrained by conscience, join the ranks, to sell exemption certificates, or with a keen eye to business, as the leading Boston anti-vaccinist, who specializes in a line of "medical practice" which he cannot advertise in this state through legislative restriction.

So long as the opponents confine their arguments to theories, no harm is done. Through a publicity service they keep informed of all illnesses and deaths which by even the wildest flight of fancy could be ascribed to vaccination. Their effective arguments against vaccination are based on the severe sore arms and loss of wage subsequent to vaccination improperly performed in factories and tenement houses in time of epidemics. We can more fully appreciate the statement of an anti-vaccinist candidate for the legislature, this fall, who said: "I expect an increased vote on account of the many vaccinations done in the mills." The real danger from this agitation is that the legislative campaign may be successful and annul our only existing law on the subject, for our legislators may be moved by arguments based on prejudice and falsehood as by truth.

The manner of combatting opposition to vaccination is to vaccinate well, and I would predict that twenty years of efficient vaccination in this state would silence all opposition.

Vaccinia is a disease communicable by inoculation, pursuing a definite course, and conferring immunity against smallpox for a varying period. Peculiar resistance may be manifested according to previous diseases or vaccinations, to innate or inherited characters, or to a number of intercurrent circumstances. In people previously unvaccinated, the eruption begins seventy-two hours after inoculation as a papule, and is fully apparent on the fifth day as a vesicle; on the seventh it has reached maturity, when it is a flat umbilicated vesicle surrounded by a rose red areola. This is the positive and unvarying picture of a successful primary vaccination, "A section of a pearl on a rose leaf." The celebrated wit, Charles James Fox, meeting Dr. Jenner in a large gathering said to him, "Tell me, Dr. Jenner, what is your vaccination like?" Exactly like a section of a pearl on a rose leaf," was the reply.

Crusting of the vesicle begins about the eleventh day and the crust is exfoliated from the twenty-first to the twenty-eighth day, leaving an indelible and characteristic scar, at first red, bleaching with time to white, sharply defined, with distinct pitting.

The "raspberry excrescence" is not infrequently seen three to seven days after inoculation. It becomes red, hard, and naevoid and may persist for months, leaving no scar, and conferring no protection. Its occurrence demands another operation.

THE TECHNIQUE OF VACCINATION.

To learn the technique of authoritative sources, a questionnaire was sent to the four medical schools in Massachusetts. The following replies were received:

Harvard, informant, Dr. M. J. Rosenau. Vaccination is taught practically and theoretically. Technique, incision; sharp needle—really a scratch. Vaccine, that licensed by the govern-

* Read at a meeting of the South Bristol District Medical Society, Fall River, November 13, 1913.

ment. Each student vaccinates one or more persons. Studies progress of the take to scar formation. Two insertions are made, each about three quarters of an inch long and about one inch apart. Students also visit the vaccine farm and see the propagation of the virus. "I spend perhaps, all told, six hours upon the subject of vaccination."

Dr. Rosenau is emphatic for incision and says that scarification is discouraged as dangerous; that it is forbidden by law in Germany.

Tufts, informant, Dr. W. R. P. Emerson. Taught practically at the clinic. Technique, scarify with needle; apply a drop of vaccine and allow to dry; gauze and adhesive tape dressing. Two scarifications are made. Mass. state vaccine is advised. Two insertions are made, ¼cm. in diameter, 1½ inch apart. Patients return in one week; students see them in all stages.

Similar inquiries with an additional question on revaccination were sent to the Surgeon Generals of the War, and the Navy Department, and Public Health Service with these responses:

War Department, informant, Capt. Albert G. Love. Technique: area cleansed with green soap then alcohol; dried with cotton or gauze; abrasions made by scraping or scratching on the selected area. Abrasions, three, one inch apart. Instrument ivory point or sterile scalped. Dressing, sterile gauze, perferably, sometimes vaccine shield. Dressing changed as often as necessary to keep it clean and in good condition; if the vaccination is successful the second dressing is always sterile gauze. Source of vaccine, large manufacturers of the country. If primary vaccination fails, the process is repeated in a reasonable time and is again repeated if the second attempt fails. In practice, practically all men upon enlistment and re-enlistment are vaccinated.

Navy Department, Surgeon General C. F. Stokes. No uniform technique is prescribed. Vaccine points usually employed; source varies. All recruits are vaccinated and repeated until the medical officer is convinced that the person is protected. Crews of ships are inspected from time to time for vaccination and in the event of an epidemic all persons are vaccinated.

Public Health Service, Asst. Surgeon General J. W. Kerr. "There is a general agreement that the best method of vaccination is the simplest and in this respect scarificaton has a distinct advantage; the use of vaccination shields should be avoided and aseptic bandages used."

This department furnishes the information that government licenses for propagation of vaccines have been issued to nine manufacturers.

Absolute cleanliness with a minimum of injury to the skin with aseptic protection during the development of the vesicle until scar formation, are essential to a proper vaccination. Rosenau[1] writes: "The operation may be compared to the transfer of a culture in a bacteriological laboratory. Precisely similar precautions to prevent contamination must be used in both cases. Vaccination must be considered as a surgical problem. No person unfamiliar with surgical cleanliness should be permitted to perform this "little" operation. "The scar should not be regarded as a deformity; to the sanitarian a typical vaccine scar is a sanitary dimple."

Dr. William Osler[2] refuses to vaccinate on the leg unless the patient will agree to remain in bed during the course of the vaccination.

After a discouraging experience with leg vaccination, I now refuse to vaccinate unless the deltoid site be agreed upon. Here inspection is easy, trauma is less likely to occur, and if infection follows, it runs a milder course.

I mention the shield only to condemn it. It is bulky, and invites violence. It often becomes loosened and scrapes the vesicle; it prevents radiation and produces the effects of a poultice; and among the poor it is loaned about to different children, often heavily coated with purulent secretions.

The arm having been dressed after the operation, the patient should return in seven days, or earlier, should constitutional or severe local symptoms appear. The dressing should be removed and the physician look for "a section of a pearl on a rose leaf." If present a bland ointmet with sterile dressing is applied, and in this manner the lesion is cared for until it is dry. If the vesicle has not matured and a mere scratch remain, if we revaccinate the patient in a week or two we may expect to see at the site of the first attempt an awaking which aroused and runs a short course synchronously with the second inoculation, through local anaphylaxis.

When the scar is seen then may a certificate of successful vaccination be given, and not until then. A vaccinated patient should be under the observation and guidance of the vaccinator until all chance of coccogenous infection is past.

Three illustrative cases.

CASE 1. B. K., aged four; vaccinated in the last week of May, 1912; tetanic convulsions appeared June 15; brought to hospital on 16, very dirty, with foul vaccinal wound; no sign of having worn protective dressing; died on 17; death certificate signed "Tetanus following vaccination."

CASE 2. Mary B. March 17, 1913, her four-year-old son was found ill with smallpox; she was "vaccinated" (her arm was scratched with a point), and she accompanied the little son to the hospital to care for him; she developed a severe cellulitis from the point of "vaccination" involving the whole arm, and on April 5 became ill with smallpox.

CASE 3. E. B., thirty years old; four times he has been vaccinated in cotton mills during four epidemics, lost altogether eleven weeks' work, convalescing; his mother has smallpox of fourteen days' duration; the son became ill today (Aug. 25, 1913).

In the first case, B. K., it seems that the most elementary attention to cleanliness could have prevented the tragic sequence.

The same can be said of M. B. The coccogenous infection killed the vaccine bodies, and variolous infection followed.

E. B. has my heartiest sympathy, in that risking his life, in four vaccinations in a dusty mill, all unsuccessful, with eleven weeks of suffering and loss of wage, he did not acquire immunity; I rejoice that he survived and congratulate him on finally achieving smallpox, which will put him beyond the reach of factory vaccinators in the future. You of Fall River appreciate how poorly factory vaccination is done, and the invalidism that follows. The bad results are interpreted by the laity as evidences of the true vaccinal course, and as the operator does not see the patient a second time, the unhappy victim goes on his way to expose himself perhaps recklessly to infection. If he have variola, his experience is capitalized by the opponents of vaccination.

In Dr. Jenner's time it was believed that the immunity conferred by vaccination lasted through life; subsequent observation has shown this to be within wide ranges.

Theobald Smith[3] has recently explained the variation in this way: "It is now well known that vaccination protects only for a limited period. The body forced to produce a variety of antibodies under pressure is not likely to continue such manufacture indefinitely after the stimulus is removed. Nature is not lavish in producing unused commodities. Animals naturally immune do not carry an appreciable quantity of immune bodies about. Their protection is guaranteed by more economical processes of life of which we know as yet very little. The length of time elapsing between vaccination and exposure, therefore, is of great significance in the success or failure of protection. . . . There is the principle of active immunization itself which must be carefully kept before us. When we discuss vaccination as a preventive, we mostly fail to take into account that we are asking something of the individual to be vaccinated, rather than giving him some thing. We are asking his tissues to go through the preliminary process of training to meet some future emergency. Vaccination is a process of education for being better prepared to meet an invasion at once, before it has grown to any dimensions. We have no reason to suppose that the characteristics of the body will be materially and permanently altered by such a training. If the body is below par in the supplying of immune bodies, it is likely to remain so, despite the vaccination. Of two individuals treated preventively alike, one may be able to cope successfully with a large or more virulent dose than the other. The plane of immunity of both is raised by vaccination, but unequally so, and in proportion to their natural endowments."

REVACCINATION.

Kitasato[4], 931 revaccinations.

After 1 year	14	per cent.	successful
" 2 years	33	" "	"
" 3 "	47	" "	"
" 4 "	57	" "	"
" 5 "	51	" "	"
" 6 "	64	" "	"
" 7 "	73	" "	"
" 8 "	80	" "	"
" 9 "	85	" "	"
" 10 "	89	" "	"

Lescohier[5] in a series of 251 revaccinations obtained practically the same results. Millard[6] states that the government report of the German Confederacy shows from 91 to 93% successful revaccinations after ten years. It is manifest that protection is exhausted in one half of all people five years after inoculation and in the rest at the latest about the tenth year. The power to modify the disease continues into later life.

Vaccination is clearly indicated at five or at the latest, ten year intervals. The results of periodic vaccinations support this statement. A recent writer estimated that the unvaccinated in England was rapidly increasing, due to parents availing themselves of the "conscience clause" and that a few years would prepare the country for a wide spread epidemic. Since our state law requires vaccination only as a requirement on entering school, and except on possible exposure, no revaccination is done, it is evident that our cities are practically unprotected. True, our immigrants before mentioned have borne the burden, so far being virgin soil for that seed. The devaccinated have some immunity and have shown the resistance.

The local response to revaccination varies in proportion to the amount of ferment remaining from the reaction induced by the primary inoculation. We may observe the typical primary picture, showing complete loss of immunity; or a rapid course of a few days; or a small papule or transient erythema may be the only sign, and leaving no scar.

Dr. Jenner and his immediate successors made one puncture or incision. In seeking to prolong immunity when smallpox among the vaccinated occurred multiple incisions were employed, and have been generally employed throughout Europe ever since. Bonn[7], Immermann[7], Pfeiffer[7], Seaton[8], Simon[8], Roger[9] and Cory[10] agree that a constant relation exists between the number of scars and the degree of immunity afforded.

The figures of Marson are familiar:

	Cases.	Deaths.	Mort. %
Unvaccinated	2654	996	37.2
Stated to be vaccinated but with no scar	290	74	25.5
One scar	1357	125	9.2
Two scars	888	53	5.9
Three scars	274	10	3.6
Four or more scars	268	3	1.1

Rosenau in his recent text book says: "The number of incisions has an important bearing on the probability of the take as well as protection; it is not wise to depend on one; the relation to the number of vesicles and the amount of reaction to the degree and length of immunity has not been worked out."

American vaccinators generally have been content with one puncture and regard additional punctures as assurances of a successful take.

Size of Scar to Immunity: Russell, Marson and Gayton are quoted by Hanna[11] as believing that the quality and size of the scar area have an important bearing on the amount and extent of the eruption and consequently on the severity of the disease. Corlett[12] believes the protection to be proportional to the size of the scar.

Hanna in a study of the scar area in 943 revaccinated persons who developed smallpox in Liverpool drew the same conclusions.

These phases seemed to me to be of unusual interest and well worth further investigation. Marson's figures, and the continued European practice of multiple incisions with the low incidence of smallpox would warrant further study. For this purpose these questions were submitted to two biologists and two clinicians:

Is greater vaccinal immunity conferred by multiple incisions?

Is the degree of resulting immunity to be estimated by the diameter of the scar?

Dr. Simon Flexner replied that he was unable to answer the questions.

Dr. Alvah H. Doty answered: "I am entirely satisfied that multiple punctures are unnecessary and that all the immunity that vaccination affords can be obtained by a single scarification properly performed with tested virus. This practice has been followed by the Department of Health of New York with the most satisfactory results and is accepted throughout the U. S. and is becoming generally accepted throughout Europe.

"I do not believe that the degree of immunity can be estimated by the diameter of the scar or scars provided the latter are of reasonable size and typical. . . I believe it is unnecessary and a mistake to make the scarification too large. The success of the operation depending rather on the character of the virus and having it well rubbed in without the too free escape of blood."

Dr. Theobald Smith: "I would say that immunity is strengthened in proportion to the number of vaccinal punctures. This fact has been determined by observation. I am not sure that we can explain it on the basis of our present knowledge of immunity.

"As regards the size of the scar, a number of factors may enter. The pustule may have been disturbed; the scab may have been torn off and the ulcer increased in size. It is also possible that when two vesicles are close together they may fuse and thereby increase the size of the scar. The final scar may be increased by injury due to secondary infection of the vesicle. In any of these cases, it would be difficult to say how far the immunity had been influenced."

Dr. John H. McCollom: "It seems to me that a longer immunity is conferred by making three scarifications. . . I can give you no definite figures on the matter, but after a very careful study of the whole subject, I am thoroughly convinced that there should always be three insertions of virus when a person is vaccinated. The experience of the German Empire is confirmatory. It is the custom there in many of the cities to vaccinate a person on each arm and to make three incisions. I never yet have seen a person with six scarifications, no matter how long a time had elapsed since vaccination was performed, have smallpox.

"In regard to your second question so far as the appearance of the scar is concerned, that is a question that cannot be definitely answered. Three reasonably good scars is a fairly sure indication of protection, but the mistake must not be made of thinking that because a person has a large scar, it is an indication of successful vaccination." Here follows the description of the scar resulting from a negative take and the letter concludes thus: "Physicians and the public must be carefully taught that vaccination is not such a simple matter; that it requires an expert to state definitely whether vaccination has been successful or not."

Vaccine: The State Board of Health has propagated and issued vaccine to the physicians of the state since 1904; in the years 1904-1912, 449,378 tubes were dispensed, and from Dec. 1, 1912 to Oct. 14, 1913, 102,942 tubes; a few complaints have been made, which on investigation have always been found to be based on errors of technique rather than to defects in the vaccine.

For more than a year I have used this vaccine exclusively on all patients and on myself. I have been able to get a take in every primary vaccination on the first trial with slight constitutional reaction.

CONCLUSIONS.

Vaccination is a surgical procedure; hence demands surgical asepsis.

The patient must be under the supervision of the physician until scar formation, when a certificate may be given.

He should be told that his immunity is for a limited time; if liable to exposure to be revaccinated.

As those countries are most free from smallpox where vaccination is regularly imposed, a revaccination of all persons in a state should be required at stated intervals.

Vaccination should be done with a minimum of trauma.

The experience of most observers warrants two or more incisions.

Vaccination efficiently performed protects against smallpox.

Vaccination efficiently performed silences opposition.

CORRELATIONS OF CEREBRO-SPINAL FLUID EXAMINATIONS WITH PSYCHIATRIC DIAGNOSES. A STUDY OF 140 CASES.*

BY MARY ELIZABETH MORSE, M.D., WORCESTER, MASS.

Assistant Pathologist, Worcester State Hospital.

[From the Laboratory of the Worcester State Hospital,]

THE scarcity of actual correlations between findings in the cerebrospinal fluid and psychiatric diagnoses in any considerable series of cases makes of value a review of the results in a large hospital for the insane. The object of the present study has been to discover of how much value examinations of the cerebrospinal fluid have been in changing, confirming or making more accurate the psychiatric diagnoses. The focal points of interest in this connection are, of course, the diagnosis of paresis and of cerebral syphilis. It may be said in a general way that this review has shown that paresis is not actually as frequent as would appear from purely clinical examination, and that the cases which are most likely to be mistaken for it are Korsakow's psychosis, cerebral arteriosclerosis and cerebral syphilis.

The method† adopted in this hospital is to have a Wassermann test made on the serum of each new patient unless this has been recently done in another institution. If the result is positive, and also in negative cases in which the symptoms or signs are suggestive, the cerebrospinal fluid is examined for the Wassermann reaction, cytology and globulin content. Similar tests are being carried out also on old patients as rapidly as possible. The Wassermann reactions are done at the laboratory of serum diagnosis of the Harvard Medical School. The remainder of the examination, except the differential count, may be done by a non-medical laboratory assistant, who is familiar with blood counting and elementary chemistry.[1]

Statistics. The period chosen for study was the year ending Jan. 1, 1914. During this time 626 Wassermann reactions have been done on the sera of 618 patients, 445 of whom were admitted in 1913, and 173 before that time. The 1913 admissions form an unselected group from which may be estimated the frequency of syphilis in patients admitted to this hospital. The results are:

Wassermann reaction in the serum positive in 80 cases (18%).

Wassermann reaction in the serum negative in 362 cases (81.3%).

Wassermann reaction in the serum doubtful in 3 cases (0.7%).

This percentage of positive sera is lower than that of Paine,[2] who in his study of 200 consecutive admissions to the Danvers State Hospital found 24.5% positive.

During the year ending Jan. 1, 1914, 142 cerebro-spinal fluids from 140 patients have been examined for the Wassermann reaction. Of the 76 specimens from 1913 admissions, 33 (43.4%) gave a positive, 43 (56.6%) a negative result.

CLASSIFICATION.

We have used as a basis of our grouping of the fluids for study, the diagnosis given by the physician on the card accompanying the specimen to the laboratory, combined with the serological and cytological findings in the fluid. It must be emphasized in the beginning that in many instances this clinical diagnosis represents not the final, but the provisional diagnosis after the routine physical and mental examination, and is made with the reservation that it may be changed by the serological and cytological evidence.

* Worcester State Hospital Contribution No. 20 (1914. 1).

† METHOD.—The following is the method adopted for the Wassermann reaction: "Three antigens differing in fixing power are used for each specimen. Two are from human hearts and are reinforced with cholesterin; the third is the alcoholic extract from a fetal syphilitic liver. The complement, which is ten per cent. guinea-pigs' serum, is titrated daily to determine the unit; two units are used in the test. The amboceptor is titrated against .5 cc. of 10 per cent. guinea-pigs' complement in order to determine the amboceptric unit. Two units are used in the test. The amboceptor value is re-determined before each test. Washed sheep's corpuscles, are made up with normal salt solution to 5 per cent. suspension. Five-tenths of a cubic centimeter is used."

"The following controls are used for each test; a strongly positive syphilitic serum; a weakly positive serum; a negative serum, and tubes containing double the amount of each antigen."

"All doubtful cases are repeated at the next test, and if there is sufficient serum, varying amounts of antigen and serum are used, so that the resulting test rarely gives a doubtful result."

The Noguchi test for globulin was used, and was performed as follows: to 0.2 cc. of cerebro-spinal fluid, 0.5 cc. of a 10 per cent. solution of butyric acid in normal salt solution is added, and the mixture heated to boiling. One-half a cc. of normal sodium hydroxide solution is added, and the tube boiled slightly. A flocculent precipitate within 15 minutes indicates a positive result.

For the cell count in the fresh fluid, 0.1 cc. of 3 per cent. acetic acid and 1 cc. of cerebro-spinal fluid (well shaken) are mixed in a white blood counter, and ten fields are counted.

The sediment is prepared for differential counting by the Alzheimer method, *i.e.* by adding to 3 or 4 cc. of cerebro-spinal fluid twice its volume of 95 per cent. alcohol, centrifuging for one hour at high speed, and hardening the precipitate in absolute alcohol, followed by absolute alcohol and ether. The coagulum is removed from the centrifuge tube with a pointed glass rod; embedded in celloidin; cut in sections 7 m. thick, and stained with pyronin-methyl-green. In fluids showing a high or moderate pleocytosis 200 cells were counted. When cells were present in normal or slightly increased numbers, several sections (5 to 8) were gone over carefully and the actual number of each variety of cell present was stated.

The following classification was adopted:—

1. Cases diagnosed clinically as paresis, with which the findings in the fluid were on the whole in accord; 47 cases.

2. Cases diagnosed as paresis, in which the spinal fluid was negative or doubtful; 13 cases.

3. Cases in which the fluid was sent in to the laboratory with the diagnosis "Paresis?"; 20 cases.

4. Cases of organic dementia, including cerebral syphilis; 15 cases.

5. Alcoholic group, including both the acute and chronic forms; 10 cases.

6. Negative fluids from a variety of conditions, including manic-depressive insanity, dementia precox, imbecility, etc. These will not be further considered here.

It is obvious that in this group there is considerable latitude of judgment given on both the clinical and the laboratory sides, but at least it brings out the difficulties of diagnosis and the type of case in which the examination of the cerebro-spinal fluid is of particular value.

Group 1. In this group of 47 cases the Wassermann reaction on the serum was positive in 41 cases, negative in 4, and not recorded in 2 cases. The cerebro-spinal fluid was positive in 36 cases, negative in 9, and not recorded in 2 cases. The serum and fluid were both positive in 36 cases, the serum positive and fluid negative in 5 cases, the serum negative (tested twice) and fluid positive in one case; both serum and fluid negative in 3 cases, and one or the other not recorded in 2 cases.

All these fluids except one, however, showed a pleocytosis, and all but two contained plasma cells. All gave positive ammonium sulphate or Noguchi reactions, usually in high dilutions.

The Wassermann reactions, with the one exception mentioned have not been repeated in cases giving negative results. We should not consider that a single negative report on the fluid where it is impracticable to use "auswertung" methods[3] would weigh decisively against the diagnosis of paresis, if the cytology and clinical picture were typical. Cases showing a positive reaction in the serum and a negative one in the fluid, with a positive cytology, suggest, of course, cerebral syphilis in contradistinction to paresis, and cases in which the serum and fluid are both negative can be put in the paresis group only if the clinical and cytological evidence is very strong.

Schoenhais[4] has recently reported four cases of clinically typical paresis, in which serum and fluid gave repeated negative reactions, but in which the globulin test and the cytology were positive. In three of the cases the diagnosis of paresis was verified by autopsy. All the cases were of the slowly progressing form.

Two of the cases in this series having negative reactions in both serum and fluid are clinically advanced cases of the dementing form of paresis of at least one and a half and two and a half years' duration, respectively. One shows Argyll-Robertson pupils, tremors and practically normal knee kicks; the other slurring speech, rigid pupils, absent knee kicks, incoordination and a positive Romberg sign. The third is apparently an early case of the expansive form, with unequal pupils, reacting sluggishly to light, exaggerated and unequal knee kicks, unsteadiness and tremors.

Of the cases with the Wassermann positive in the serum and negative in the cerebro-spinal fluid, it may be said in a general way that the clinical picture and physical signs are more in accordance with paresis than with cerebral syphilis. In two cases the infection was respectively at least twenty and twenty-three years before the beginning of the psychosis; in the other three cases, the date of infection is unknown. The onset was gradual in all cases. Four of the patients are in an advanced stage of dementia, while the fifth is apparently an early case of the expansive form. Two of the patients have Argyll-Robertson pupils, two contracted pupils, inactive to light, and reacting only slightly to accommodation; the fourth has active pupils. One of the cases is of eleven years' duration.

Group 2. In the second group, those cases diagnosed clinically as paresis, but with doubtful or negative findings in the cerebro-spinal fluid, are two cases typical clinically of the expansive form of paresis. In one the fluid was taken on the day of death, in the other a week before. The sera were both positive, one fluid positive, the other negative. The globulin reactions were slight, the cell counts within normal limits and the sediments showed small numbers of lymphocytes and endothelial cells, with, in one case, possible plasma cells. Unfortunately, no autopsies were obtained, but it seems probable that the terminal stage of the disease may account for the indefinite findings.

In this group is also one other case with anomalous findings: a patient with the clinical symptoms of the dementing form of paresis, with pupils reacting sluggishly to light, exaggerated knee jerks, unequal facial innervation, and slight Romberg sign. The Wassermann reaction was negative in the serum, positive in the cerebro-spinal fluid. The examination of the first specimen of fluid showed a slight Noguchi reaction, a slight cell increase consisting of lymphocytes with a few doubtful plasma cells. The second specimen, taken a month later, gave negative ammonium sulphate and Noguchi reactions, a normal cell count and only a few lymphocytes in the sediment.

Another patient in this series has the following history: 58 years old, a painter for 25 years. In the Worcester State Hospital four and a half years. Has had both lues and numerous attacks of lead colic and has used alcohol in moderation. Six months before admission patient lost interest, became reticent, and irritable, and had attacks of dizziness. On admission he was quiet, euphoric, with delusions

of persecution and reference. He was imperfectly oriented for time and place; had but slight grasp on his surroundings and no insight. Memory was fair; speech somewhat slurring, pupils active, gait unsteady, knee jerks exaggerated, suggestive Romberg's sign. The patient is in a stationary condition, and although quite irritable, is able to work regularly. The Wassermann reaction was negative in the serum, doubtful in the cerebro-spinal fluid. The latter gave negative globulin tests, but a slight lymphocytosis. It is possible that this may be a case of lead encephalitis, although there is no very definite evidence to support this view.

The revised diagnoses in the other cases of this series are: Korsakow's psychosis, 3 cases; acute alcoholic delirium (terminating fatally, no autopsy), 1 case; dementia precox, 3 cases; unclassified depression, 1 case.

On examination of the histories of the patients who proved not to be paretics, the reason for the diagnosis of general praralysis is in most cases obvious. All the cases presented more or less suggestive physical signs, ranging from pupillary inequality, tremors or changes in the reflexes to sluggish reaction to light, speech defect, and in some of the alcoholic cases ataxia. In four cases also the Wassermann reaction in the serum was positive, in two others there was a history of syphilis, while in four syphilis was denied and the Wassermann reaction in the serum was negative. Another fact standing out prominently in this group is alcoholism, which was present in all but one of the cases.

Group 3, in which the fluids were sent to the laboratory with "question of general paralysis," comprises 20 cases. The diagnosis was confirmed in five cases by positive Wassermann reactions in serum and fluid and typical cytology in the latter.

One of these, a man of 61 years, had previously been diagnosed an early senile dementia. The diagnosis of paresis in this case has been substantiated by autopsy. Another patient, a woman, 54 years old, was admitted after a suicidal attempt, showing depression with psychomotor retardation, but without physical signs. The first diagnosis was manic-depressive, or a depression of arteriosclerotic origin. The patient is now dementing, is confused and excitable, and definite signs have appeared.

One case of clinical paresis examined a week before death showed conditions somewhat similar to the terminal cases mentioned in Group 2. The serum gave a negative reaction, the fluid a suggestion of a positive. The globulin was considerably increased, the cell count normal, and the sediment contained small numbers of lymphocytes and endothelial cells. The revised diagnoses in this group are: Alcoholic hallucinosis, 2 cases; acute alcoholic delirium, 1 case; alcoholic deterioration, 1 case; dementia precox, 6; manic-depressive with deterioration, 1 case; manic phase of manic-depressive insanity, 1 case.

A study of the histories of these cases brings out the frequency of the same three factors noted in the previous group,—physical signs, syphilis and alcohol. Ten patients in addition to those in whom the diagnosis of paresis was confirmed, had positive Wassermann reactions in the serum, one other gave a history of syphilis, one had signs of the disease, two denied lues and had negative Wassermann reactions, and in one case no clinical history was obtained. Nine patients, exclusive of the paretics, had a history of alcoholism.

Group 4, that of the organic dementias, contains 15 cases. The examination of the blood and cerebro-spinal fluid has helped considerably to differentiate the etiology of these cases. In seven the Wassermann reaction was positive in the serum, and negative in the cerebro-spinal fluid. Two of these showed negative globulin reactions and negative cytology, the other five a positive globulin reaction, lymphocytosis, with, in three cases, the addition of plasma cells. One of these patients, diagnosed paresis during life, was found at autopsy to have cerebral gummata. In one case in which the serum was not recorded the fluid gave a negative Wassermann reaction, but a positive globulin test and a lymphocytosis. One case presented a negative Wassermann reaction in the blood and a positive in the fluid, with increased globulin content and a lymphocytosis. In five cases the serum and fluid were entirely negative. In five of this group, therefore, in addition to the autopsied case, it seems permissible to assume a syphilitic etiology for the trouble.

Group 5. Ten fluids were sent in from patients with the diagnosis of various forms of alcoholic psychoses: acute alcoholic hallucinosis, 5 cases; chronic alcoholic hallucinosis, 1 case; alcoholic deterioration, 2 cases; Korsakow's syndrome and alcoholic traumatic, each 1 case. One of these cases had a positive Wassermann reaction in the serum, and a negative one in the fluid, but an increase of globulin and a lymphocytosis. One other had similar findings, with the exception that the Wassermann reaction in the fluid is not recorded. Four patients had positive Wassermann reactions in the serum, but cerebro-spinal fluids negative serologically and cytologically. One case with a negative reaction in the serum but in whom the Wassermann reaction in the fluid was not recorded, had a slight increase in globulin, but negative cytology. One case gave negative reactions to all the tests, and one an isolated positive Wassermann in the spinal fluid. One patient on whom the diagnosis of alcoholic hallucinosis was made, was found to have a positive Wassermann reaction in serum and cerebro-spinal fluid, an increase of globulin, and a pleocytosis, with the presence of plasma cells. It is impossible to exclude cerebral syphilis in the alcoholic cases who show a positive Wassermann reaction in the serum, a lymphocytosis and globulin reaction in the cerebro-spinal fluid, and doubtful physical signs.

DISCUSSION.

In reviewing these groups, it is found that among 80 patients in whom the diagnosis of paresis was made definitely or in whom a suspicion of it was entertained, in 57 at the most (71%) the diagnosis appears to be confirmed after examination of the serum and cerebro-spinal fluid. In the 60 cases in which the diagnosis was made definitely, it seems to be substantiated by serological and cytological evidence in 50 cases, or 83%.

On the other hand, three cases of paresis have been discovered by the routine examination of the serum and cerebro-spinal fluid in patients diagnosed on admission as senile dementia, arteriosclerotic depression and alcoholic hallucinosis.

The groups into which the non-paretic cases fall are: the alcoholic, 10; the dementia precox, 9; the manic-depressive, 2; unclassified depression and undiagnosed, 1 each. The revised diagnosis in all the cases, except possibly the Korsakows, would doubtless have been attained by clinical observation alone in the course of time, but for rapid elimination of the suspicion of paresis, the serological and cytological examination of the cerebro-spinal fluid is essential. It is also a common experience in large hospitals that there are on the chronic wards certain demented patients who are supposed to be long-standing cases of paresis, the diagnosis having been made on their admission in pre-Wassermann days, and never challenged. When their sera and fluids are examined, however, the results in a certain proportion of cases are found not to be in accord with the diagnoses and the cases appear on closer inspection to be cerebral arteriosclerosis or syphilis, or Korsakow's psychosis.

Correlations of clinical and autopsy findings from the Danvers[5] and the Worcester State Hospitals[6] in pre-Wassermann days have shown that there is a positive error of about 15% in the clinical diagnosis of paresis. The study of clinical diagnoses before and after examination of the serum and cerebro-spinal fluid goes to prove the same point, *i.e.* that paresis is actually not as frequent as it appears to be from purely clinical observation.

Since Wassermann tests and cerebro-spinal fluid examinations have been commenced, however, the tendency in this institution at least, has been toward more reserve in the diagnosis of paresis, and more care has been exercised in making a differential diagnosis, particularly from cerebral syphilis and arteriosclerosis.

CONCLUSIONS.

Our conclusions may be summarized as follows:

1. Examination of the serum and cerebro-spinal fluid leads to a reduction in the number of cases diagnosed as general paralysis.

2. The cases which have been found most difficult to differentiate from paresis without examination of the serum and cerebro-spinal fluid are cerebral syphilis and arteriosclerosis and Korsakow's psychosis. In regard to cerebral syphilis, however, it must be said that although the findings in the serum and cerebro-spinal fluid are supposed to be sufficiently characteristic to permit a differential diagnosis from paresis, in the individual case they frequently leave one in doubt.

3. In a large insane hospital the routine examination of the serum and cerebro-spinal fluid finds, perhaps, its most immediate value in the rapid confirmation or elimination of the suspicion of paresis in new patients and in revision of the diagnoses of certain patients admitted in pre-Wassermann days.

Thanks are due to the staff for help in collecting the clinical data.

TWO CASES OF LUNG ABSCESS CURED BY OPERATION.

BY WYMAN WHITTEMORE, M.D., BOSTON.

Assistant Surgeon to Out-Patients, Massachusetts General Hospital.

These two cases are reported because in each an abscess of the lung followed immediately after taking ether. One patient had been operated on for a deviated septum and the other had had several teeth extracted. It seems probable that both these cases were due to aspiration of some infective substance.

Both cases are perfectly well at the present time. The first case was operated on a year and three months ago and the second four months ago.

I criticize my technic in the first case at the present time because the operation was done at one sitting. The lung seemed to be adherent to the lower half of the pleura that was exposed in the field of operation, but although I stitched the lung to the pleura before opening into the abscess, yet this patient developed an empyema two weeks after the operation, which I feel was due to leakage of septic material into the pleural cavity. This necessitated a second operation, from which the patient made a speedy recovery.

I think the technic I used in the second case a much safer one. In this case at the first opera-

tion, after exposing the pleura, I placed several gauze sponges against it, and did nothing else except suture the skin and muscle flap back into place. At the second operation, five days later, I found the lung very adherent to the pleura, and after draining the abscess the patient made an uninterrupted convalescence.

Case 1. A married woman of 21, entered Sept. 17, 1912.

F. H. Mother, father, one brother and husband well. Married fifteen months. No children. No miscarriages. No tuberculosis, neoplasm or neuroses. No exposure to tuberculosis.

P. H. Measles, scarlet fever, whooping cough, before five years of age, "nervous prostration" at 18, brought on by over-work and worry; treated for three months with good recovery. Otherwise always well and strong, until November, 1911. No chronic cough. Took cold easily. Cta. at 13. Appetite always good. Bowels constipated. Weight 143.

P. I. Oct. 31, 1911, took ether and had 15 teeth out. Nov. 1, "caught cold." Nov. 2, went to bed with sharp pain, worse on cough in lower left axilla and a dull heavy weight in front of left chest above breast. Coughed night and day, raised thick, dark brown sputum. Was in bed eight weeks, cough gradually lessening and sputum gradually getting lighter in color until it became white and watery, "temperature irregular, 98.6-101, pulse normal, appetite and nutrition good." Cough never entirely ceased but she was up and about and in Jan., 1912, started housekeeping again, and was in fairly good health until March, 1912.

On March 23, 1912, had two hemorrhages within half an hour, raising about 2½ cups of dark red blood.

April 5, 1912, was sent to Sharon Sanitarium with a diagnosis of tuberculosis. In bed for two days after which she was up and about until May 15 when she was discharged against advice.

Patient states that repeated examinations for tubercle bacilli were negative. Within a week from the time of discharge was in bed again with pleurisy, up in two weeks and has remained in fairly good health except that cough had continued. Took cold in August which was followed by return of sputum, cough and pleurisy. Five days before entrance, taken with sudden sharp pain in upper left chest, more severe than pleurisy pain. Felt a gurgling in chest, was frightened, could not breathe for a little while. Similar attack two days later. The amount of cough and sputum has varied greatly but has never been entirely free from cough for eleven months and at times has raised as much as two cupfuls in twenty-four hours. Has slept well except for being disturbed by cough.

P. E. W. D. woman, with clear skin and mucous membranes of good color; pupils circular, equal, and react normally. Superficial lymph nodes negative. Tongue clean. Many teeth gone. No pyorrhea. Throat a little reddened. Heart, dullness from midsternum, 3 cm. to right, 12 cm. to left, 2 cm. outside nipple line. Apex impulse felt in fifth space, inside nipple line. Sounds rapid, regular, with a soft systolic murmur heard along left sternal margin, best at second left interspace. P2 greater than A2 and plus. Pulses equal, good volume and tension. Artery walls not felt. Lung: left, in front there is a space bounded above by the first rib, internally by edge of sternum; below, by fourth rib, and externally by anterior axillary line. There is tympany, coarse gurgling râles, no coin sound, breathing harsh, prolonged expiration but not typically amphoric, cracked pot sound. Nothing abnormal heard in back. There is a small area in the region of the apex of the right lung of relative dulness, slightly increased fremitus and voice. Liver dullness sixth space to costal margin, edge not felt. Spleen not felt. Extremities normal. Knee-jerks present and equal; reports from City Board of Health, state no tubercle bacilli.

Sept. 18, whole right back slightly dull. Left back slightly tympanitic. Breath has a sickish odor, sputum not extremely foul. Tentative diagnosis, "lung abscess" following a foreign body,—an ether inhalation pneumonia or an infarct. Sept. 20, x-ray No. 21,474, a dense shadow occupies the whole of the left middle chest, base and apex clear; right lung negative. Shadow probably due to thickened pleura overlying some pathological process in lung. No foreign body seen. Sept. 22, second plate confirms above.

Sputum examination Sept. 17, slightly foul smelling, muco-purulent, with one blood streak, microscopically many bacteria, mainly cocci of various kinds, none overwhleming in predominance, no tubercle or influenza bacilli seen.

Sept. 20, muco-purulent sputum with two blood streaks, no tubercle or influenza bacilli seen.

Sept. 25, very rare elastic fibre found after boiling sputum with 10% NAOH and centrifugalizing.

Sept. 26, no change in physical condition or in symptoms. Evidence points to the presence of one or more abscesses in left lung at the level of third to fifth rib, probably near the anterior wall, probably pneumonitis about them and thickened pleura. Transferred to the surgical service:

While on the medical service the temperature varied from 98 to 99.2, pulse 90 to 100. Urine normal. Blood, Hgb. 70%; whites 12,200, red 4,264,000.

I operated on Sept. 27, 1912. Intratracheal ether. Patient placed on right side with left arm held high up, giving excellent exposure of left chest. A six-inch curved skin incision in anterior axillary line. Skin and muscle flap turned up. Third and fourth ribs exposed over an area of three inches and resected subperiosteally. Intercostal muscles tied at both ends and excised. Through the upper half of the exposed pleura normal lung was seen moving with respiration, but through the lower half of the exposed pleura, the lung did not move with respiration, was solid to the touch and seemed adherent to the pleura. Fifth rib exposed and resected as the others. Pleura stitched to this solid area of lung tissue. Trochar inserted into this lung tissue, inward and upward, thick blood, only result. Finger inserted along path of trochar and region corresponding to x-ray shadows, explored. A cavity, above and just external to the heart was broken into from which escaped a little foul-smelling pus, mixed with clotted blood. This cavity drained with rubber tube.

Patient made a good recovery from the operation with T. and P. coming down from 101 to normal and remaining normal for nine days during which time she coughed very much less but still raised a little sputum, containing streptococci and pneumococci. The discharge from tube was at first, dark bloody fluid with some muco-purulent material, later becoming entirely muco-purulent. On the tenth and eleventh days following operation T. P. began to go up and during the following week patient

ran a temperature of 101-102 at night, down to nearly normal in the morning. The physical signs on Oct. 17 showed dullness in the left back half way up to scapula. Trochar inserted in eighth interspace, in posterior axillary line, and half a bottle of thick pus evacuated.

Oct. 17, second operation; one and one-half inches of eighth rib resected, subperiosteally pleura opened with escape of a considerable amount of pus. Large rubber tube fastened in.

Patient made an excellent recovery. The discharge gradually lessened so that on November 1, 1912, the tube was left out entirely and on Nov. 4, she was discharged from the hospital.

Dec. 15, patient's doctor reports that she has been gaining strength steadily and has had no pain or cough.

Feb. 10, 1913, patient reports, there is no discharge, both wounds entirely closed, no cough, no expectoration. Has gained twenty pounds since leaving the hospital.

Nov. 17, 1913, patient writes that cough is entirely gone, side is perfectly well and she considers herself cured.

CASE 2. Age 17, single; entered the hospital Aug. 15, 1913. Office-boy.

F. H. Father, mother two brothers and two sisters well.

P. H. Measles as a child. Occasional sore-throat and cold. Appetite good. Habits, no alcohol or tobacco.

P. I. On July 23, 1913, operation on nose under ether for deviated septum. Went home a few hours later.

July 25, began to have headache, frontal region, no nasal discharge.

July 27, pain in chest. Slight cough.

Aug. 1, pain in chest worse, cough and foul sputum. Not working but up and about. Occasionally felt feverish. Cough usually started on lying down. Paroxysms of about five minutes, raising about a drachm or two of yellow sputum. Pain localized under right scapula.

P. E. W. D. N. boy, short loose cough. Skin shows marks of counter-irritation over right chest. Sclera clear, mucous membrane of pale color. Pupils, equal, regular, react normally. No glands felt. Tongue, moderate white coat. Teeth fair. Throat red. Heart, apex in fifth space, 8 cm. to left of median line, just outside nipple line. Shifts 3 cm. in left lateral position in same space. Right border 2.5 cm. to right of midsternal line. Sounds regular, good quality, no murmurs. Pulses, equal, good volume. Lungs: right anterior region at second and third ribs, dull, diminished breathing; slight bronchophony. Right posterior, corresponding region, slight dulness. At the lower angle of the scapula there is dullness and high pitched voice, a few fine and medium moist râles at the base of both lungs. Abdomen: liver dullness fifth space, to costal margin; edge not felt. Spleen and kidneys not felt. No masses, tenderness or spasm. No costo-vertebral tenderness. Extremities negative. Genitals negative.

The next day breath not foul but sputum very foul. Heart slightly displaced to left; right chest fixed, generally tympanitic. Transitory bronchial breathing above right nipple; heart sounds heard well in right axilla. There is probably an area of consolidation surrounding an abscess near root of right lung. Sputum: about 2 c.c., moderately thick, muco-purulent. Not bloody, very foul. Microscopically much pus, occasionally large gram-positive diplococci. A few streptococci in long and short chains. Some bacilli, not characteristic, no tubercle bacilli. X-ray shows dullness at right upper chest as low as fourth rib in front. Lower border of shadow is much more dense than upper border: lung markings cannot be made out in upper part. This may be due to pleural thickening. Diagnosis, abscess of lung.

Aug. 20, the boy does not seem to be absorbing much from his abscess, fairly comfortable except when coughing. Lying on right side is only position which does not induce coughing. The physical signs change rapidly from minute to minute but there is an area of dullness in region of third and fourth ribs in front where at times pure broncho-breathing is heard. T. ranges from 99-101. Urine negative. Blood, hgb. 80%, whites 34,900.

Tranferred to the surgical service:

I operated on August 21, 1913. Intratracheal ether. Patient on left side with right arm elevated. A "V" shaped incision made in right axilla with base up, about five inches across. Skin and muscle flap turned back. Fourth, fifth and sixth ribs exposed and resected subperiosteally for about three inches. Intercostal muscles ligated at both ends and excised. Pleura now exposed. Three gauze sponges laid on it and flap sutured back into position.

Five days later on August 26th, under ether, stitches removed and flap turned back. Gauze removed and pleura found very adherent to lung. On exploring the area corresponding to the shadow in the x-ray, my finger broke into a mass of soft tissue in the upper lobe with the escape of extremely foul odor and a little bloody pus. Tube fastened into cavity.

Patient made a good recovery from the operation.

Aug. 29, discharged considerable foul-smelling pus from tube. Coughs a good deal but raises very little. Temperature 98 to 100.

Sept. 15, cough very much better; does not raise anything; wound draining less.

Sept. 17, tube removed.

Sept. 19, very little discharge from sinus.

Sept. 20, discharged from hospital.

Oct. 15, patient reports in the Out-patient Department, has no cough and does not raise anything. Wound entirely healed. Is troubled slightly with shortness of breath and transferred to the medical department.

Jan. 7, 1914, patient reports that he is feeling perfectly well, except for some shortness of breath.

PROSTATECTOMY WITHOUT IRRIGATION.

BY A. E. ROCKEY, M. D., PORTLAND, OREGON.

More than a year has now passed since I published the composite method of prostatectomy without irrigation[1]. It is five years since I have irrigated the bladder after prostatectomy either in connection with the operation or during the post-operative treatment, except as I shall presently describe. Year by year I am more firmly convinced that irrigation after prostatectomy

[1] North Pacific Surgical Association, Vancouver, B. C., Dec., 1912. Printed in *Surgery, Gynecology and Obstetrics*, April, 1913.

is an error without justification in the physiology of repair.

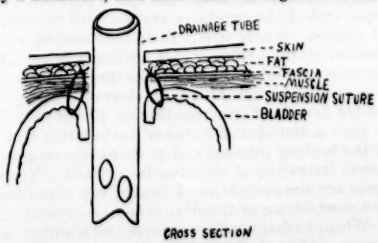
The first step in the process of wound healing is the formation of a blood clot. The clot has two important primary functions, the arrest of bleeding and the protection of the wound. These are both interfered with by irrigation. A normal blood clot is also more resistant to infection than is diluted blood. When a freshly cut surface is covered with a blood clot the healing process begins at once. Proliferation of the tissue cells readily proceeds under such kindly protection and with such normal food. Remove this by continuous irrigation and what takes place? The exposed cells are rapidly devitalized by the harsh contact with a fluid of lower specific gravity than the cell contents when water is used. By osmosis the cells become swollen, lose their plasm and die. Fortunately their dead bodies afford a measure of protection to the deeper tissues until the misdirected irrigaton has been discontinued. Like all devitalized tissue, however, this layer of dead cells is an easy prey the various saprophytic and pathogenic bacteria, whose toxines make further inroads on the reparative process. When repair is at last established by the formation of a layer of more resistant granulation tissue, its first task is to remove the enfeebled cells by phagocytosis, and cast off the dead layer as a slough. Then and not until then can repair begin in the same manner that would at once take place where the tissues are protected by a blood clot.

The purpose of the operation of prostatectomy is to remove the obstacle to urination with the least possible disturbance from the surgical procedure. Suprapubic enucleation with the finger, as it has been evolved from the methods of Fuller, Freyer and others, has at last come to be considered the method of choice by the majority of surgeons. This operation is essentially one done by the sense of touch. Between the bare index finger of the right hand, whieh bores into the capsule and conducts the various steps of the enucleation, and the two first fingers of the left hand, protected by the glove and supporting the gland through the rectum, there is such a complete recognition of texture, position, size and line of cleavage as would make an unobstructed view unnecessary. But vision at the bottom of a bloody bladder is obtained only at the expense of long incision, deep retractors and much sponging, and a necessarily prolonged operation. This statement is made only on general knowledge, and on my observation of a number of such operations by other surgeons. Not only is the view thus obtained troublesome, but retractors certainly interfere with enucleation. The common sequence of such operations is packing to control bleeding, or as recently proposed, suture of the margin of the prostatic cavity, and the use of very large drainage tubes, both of which necessarily prolong the convalescence. The sewing in of drainage tubes has recently been revived. This necessitates immediate and constant irrigation to keep the bladder clear of clots, which would otherwise stop up the tube. For years' I have insisted that long incision was not necessary for the reason that in making the enucleation the operator was to be guided entirely by the sense of touch, and that the elasticity of the bladder wall and the usual softness of the larger hypertrophy permitted the delivery of a very large gland through a small incision. An inch and a half incision is therefore all that is necessary in the usual case, and two inches for glands of very large size. While the delivery of the gland may be accomplished with a pair of sponge, tongue, goiter or placental forceps, I have found much satisfaction in the use of the forceps I have devised for this purpose

FIG. 1.—Rockey's prostatectomy forceps.

(Figure 1.) The outside of the oval fenestrum is smooth and the inside scalloped, thus ensuring a firm grasp of the enucleated gland without endangering the bladder wall. Bleeding is usually slight, but even if brisk at first, if left alone it usually stops quickly. In the rare exceptions in which bleeding is excessive, we get the advantage of the small incision; the unmolested clot soon gains support from the bladder wall and aids in the arrest of bleeding by pressure.

I have found the valvular suspension suture (Figures 2 and 3) to be of great value in supporting the bladder in an advantageous position for rapid closing, and in preventing the formaton of a pool of urine in the space of Retzius. It is introduced by passing a No. 3 plain catgut with a heavy round full curved needle through the fascia and muscle, and then through the bladder wall parallel to and about three fourths of an inch from the incised margin, which is held by a hemostat, and then back through the muscle



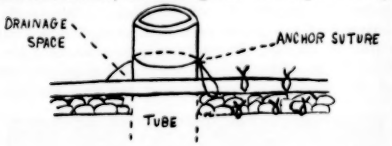


Fig. 2.

and fascia. With a single suture of this kind on each side of the incision the bladder is held in a position of valvular suspension with the edges turned in (Figure 2.) This position of the bladder greatly increases the length of the granulation tissue tract and ensures firmness in the final healing. Two or three chronic cat gut sutures in the fascia, leaving, however, abundant room for a finger size drainage tube, will diminish the danger of hernia. Two silk worm sutures above and one below, anchoring the drainage tube by

VERTICAL SECTION
Fig 3

them, as shown in Figure 3 complete the operation. Care must be taken to leave sufficient room above and below the tube for drainage; a half inch is sufficient. It is through this space that the first drainage comes, as the tube itself is quickly filled with clot. The tube must be short, usually about three inches, so that it will not press on the bottom of the bladder. It should be cut off just above the anchor suture, so that the dressings may lie flat across it.

With the abandonment of irrigation the after care of these cases has been greatly simplified. An absorbent cotton pad covered by a single layer of gauze and held by a light muslin binder, and changed six or eight times in the twenty-four hours, is all that is necessary. The ward nurse is but little troubled with the care of these cases, and special training and experience, required when irrigation is used, is not necessary. The tube should remain in place for eight or ten days. Earlier removal of the tube may disturb the healing at the vesical neck. When the tube is removed I commonly insert a large catheter through the urethra and irrigate the bladder once, and while the water is flowing introduce a large direct vision cystoscope and inspect the base of the bladder and the cavity from which the prostate was removed. By this time it is usually a small cone lined with granulation tissue prepared to bridge the space between the upper end of the prostatic urethra and the vesical mucosa. There is but little tendency to contraction of the orifice in the ordinary case. If, however, the gland was of the hard adherent type without a good line of cleavage, and yet not too firm for finger enucleation, it will be well to pass a sound a few times during this stage of the healing process, and perhaps use an occasional irrigation if detritus be present. These cases are the exception. I should say about one in ten or fifteen of those that come to operation.

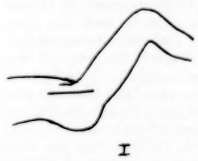
When, as frequently happens, the bladder has become infected through previous instrumentation and the urine is bloody and of bad odor, it is not possible by the most energetic irrigation to render the bladder sterile. When such cases come to the surgeon it sometimes happens that false passages have been produced and catheterization is difficult. Under these circumstances we make no effort to catheterize, and fill the bladder with water for the incision. If the condition of the patient is not favorable for enucleation local anesthesia is used, the bladder drained by a stab wound and tube, and the patient left to recuperate for operation later. When the condition of the patient is fair, the operation may be completed at once through a bladder containing this foul urine, then left without irrigating a single time, and the result will be better than with the most virgorous irrigation. With irrigation these cases commonly form large sloughs in the prostatic cavity and in the space of Retzius. Without irrigation the blood clot protects the tissues from infection, and the sloughs do not form.

We may well ask what becomes of the blood clot if it is not washed out. A portion of it may serve for the nourishment of the new granulation tissue. The remainder, after it has served it purpose as a protective and hemostat is dissolved by the urine. This dissolution keeps the urine blood-stained for a few days. It then clears up, the tube is open, the clots and bad odor are gone, and convalescence is established. The absence of irrigation apparatus permits the patient to be out of bed in a wheel chair on the second or third day, enjoying the rest and comfort that such freedom affords.

After a few days in the wheeled chair, we dress patients in painters' overalls of rather a large size, the bib making a good support for the pad of cotton which absorbs the escaping urine. This permits them to walk about the wards even while wearing the tube. The general well-being of the patient is improved by this absence of restraint. The final results are exceedingly satisfactory. The valvular suspension often closes the bladder immediately upon removal of the drainage tube, and voluntary urination in from twelve to sixteen days is not uncommon.

A NEW OPERATION FOR HIP CONTRACTURES IN POLIOMYELITIS.

BY ROBERT SOUTTER, M.D., F.A.C.S., BOSTON,

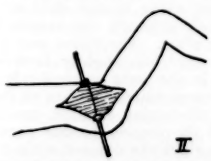


Assistant Surgeon, Children's Hospital, Boston; Instructor, Orthopedic Surgery, Harvard University.

IN poliomyelitis the usual contractures of the soft tissues at the hip hold the thigh flexed and abducted and involve a shortening of more or less all the soft tissues on the outer and anterior aspect of the region of the hip. The deformity may be slight, considerable or extreme. It is

usually accompanied by a compensatory lumbar lordosis which on account of the flexibility of the spine here makes complete correction more difficult.

Contractures of the soft tissues at the hip due to the shortening or lack of growth of the soft tissues following paralysis or injuries are sometimes easily overcome by manipulation and stretching. When they are of long standing they may not yield to tenotomies of the tendons and of the tensor fascia femoris, and myotomies are necessary. The severe contractures that need myotomies require some surgical experience on account of the vascularity and the amount of muscle tissue that must be cut before the hip will come down.



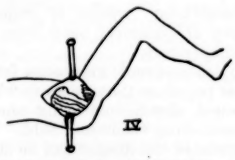
Often so many of the muscles on the anterior aspect of the thigh must be cut that finally the surgeon finds himself down on the hip joint. There are a good many difficulties and sometimes a great deal of hemorrhage, and the operation may seem very unsatisfactory, and is

I

Longitudinal incision two to three inches posterior to the anterior superior spine.

often imperfectly done. For these difficult cases and also some of the milder ones the following operation has been devised: First, a longitudinal incision is made three inches long, parallel with the long axis of the body, with its

II

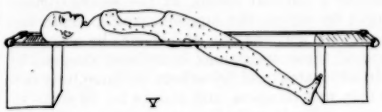


Subcutaneous tissues retracted, fascia lata exposed; the line between the retractors marks the incision transversing the fascia fibers.

middle two inches posterior to the anterior superior spine. (Fig. 1.) It is carried down to the fascia. By retracting the subcutaneous tissue the fascia is exposed from the anterior superior spine back to the trochanter. (Fig. II.) Second, the fascia is incised at right angles to the skin incision, cutting all its fibres transversely from the anterior superior spine back to the great trochanter. Third, the skin incision is next retracted in such a way as to expose the anterior superior spine. (Fig. III.) By means of an osteotome, the attached muscles and fascia are removed from the anterior superior spine subperiosteally on the inside, on the outside and

III

The anterior superior spine exposed. Attachment of muscles and fascia have been subperiosteally removed with an osteotome.



IV

Tissues formerly attached to the anterior superior spine have been pushed downward.

below; they are all pushed downward. (Fig. IV.) The hip is hyperextended backwards, pulling the tissues down with it. If the tension is great the soft tissues are pushed down by means of gauze or blunt dissector, clearing off the periosteum and soft tissues from that part of the pelvis below the anterior superior spine.

Following the operation a plaster of Paris bandage is applied to the whole leg (Fig. V.)

V

Post-operative plaster of Paris anteriorly from the nipple downward, posteriorly from the waist downward. Window in the plaster over the abdomen. Bradford frame raised on boxes to allow hyperextended position of the hip.

(contractures of the knee and ankle may be corrected first). The hip is hyperextended in order to correct the lumbar lordosis usually present in these cases. It is also adducted slightly to stretch the lateral contractures. The plaster of Paris extends from the nipple line in front and from the lower waist behind to the toes of the foot operated upon. A window may be cut in the plaster over the abdomen. The patient is put on a Bradford frame elevated to allow the legs to drop to a lower level than the hips and shoulders. The advantages of this method of procedure are as follows: There is practically no bleeding, the operation does not require much surgical skill and the contracture is definitely relieved. The muscles are not cut across; their periosteal attachment is simply moved one and one-half or two inches downward. The anterior superior spine will be found to be practically moved downward.

Clinical Department.

THE TREPHINE OPERATION IN GLAUCOMA*.

BY MYLES STANDISH, M. D., BOSTON.

Williams Professor of Ophthalmology, Harvard Medical School, etc.

THE unsatisfactory results of iridectomy in chronic cases of glaucoma have been acknowledged by all operators.

I wish to define chronic glaucoma, for the purposes of this paper, as those cases in which there is a continued, slowly increasing tension with steadily diminishing vision and field.

The progress of the disease can be stayed to a certain extent by the use of myotics, but as a rule, they lose their efficacy in the end, and the disease goes on to blindness.

When iridectomy was practically the only operation done for chronic glaucoma it was usually found that the vision diminished immediately after the operation and rarely returned to the condition just previous to the operation, and the ultimate result of many of these cases was that the progress of the disease was not stopped. This unsatisfactory state of affairs has led a number of operators in the last ten years, to devise operations by one means or another, to establish a corneal fistula at the sclero-corneal margin by which the aqueous would drain out beneath the conjunctiva, and thence be absorbed. Some of these operations have been deemed by their advocates, and by others to introduce into the case new dangers, and also to be, in some instances, difficult operations to perform. Several gentlemen, of whom Dr. Elliot of the East Indian Medical Service is the most prominent, have advocated the use of the corneal trephine to remove a disc at the sclero-corneal margin. As this method seems easier and safer than the other methods proposed, I have done nine operations following the method of Dr. Elliot with the exception that in all but two instances which will be noted, I have done a complete iridectomy through the opening made by the trephine, and am glad to accede to the request of the chairman of the committee on papers and present you with a brief resumé of these cases.

CASE 1. A woman, a Syrian, 48 years of age. first seen by me May 28, 1913.

The left eye had an attack of acute glaucoma three years before, but as far as I could determine there had been practically no local treatment, simply morphia for the pain.

At the time of this visit the right eye had good vision with normal disc.

In the left eye she had a tension of + 2, pupil 5 mm. in diameter, typical pathological depression of the disc, and great pain, which had been increasing for several weeks. Two per cent. pilocarpine only reduced the pupil to a diameter of 4½ mm. The tension was very doubtfully diminished, and the pain continued. There was no vision.

Operated on by me June 10 with Elliot's trephine. Good operative result, but after recovery she still complained of some pain and the tension was a little above normal. Pilocarpine controlled the pain.

The patient was seen by me September 13. There was some complaint of conjunctival irritation, but no pain. Over the trephine opening there existed a very large, translucent bleb, which had a base of 7 or 8 mm. in diameter, and an elevation of at least 5 mm. with conjunctival congestion in this neighborhood. Tension had not increased since June. She was using no myotic and had no severe pain. The result was a success in that otherwise we should have been obliged to have removed the eye on account of the unbearable pain.

[Later. The eye was subsequently enucleated for pain and increase of tension.]

CASE 2. Mrs. F., 48 years of age, first seen by me June 30, 1901.

There was slight increase of tension, marked depression in the disc in each eye, but not so much that one would feel sure it was pathological.

The field of the left eye was lost almost to the fixation point down and in. V.O.S. was 20/CC. Vision in the right eye was .7‡2. She was given pilocarpine and when next seen by me in September, vision in the left eye had risen to 20/C-1, and in the right eye it was .8-4. There was no shallowing of the anterior chamber, no history of rainbow halos. Tension was very doubtfully increased. Field in the right eye was slightly diminished in all directions. A collyrium of pilocarpine was prescribed and she was seen by me from time to time.

In March, 1903, vision in the right eye had risen to .9-3. The tension was normal under the myotic. The vision remained the same without lessening of the field or vision under continued use of pilocarpine, till May 6, 1908, when I found by my note that the entire nerve in the right eye was somewhat depressed, although the vessels did not cut under in any place. The vision was .9-5. May 3, 1909, the tension was slightly increased in each eye. Vision in the right eye had fallen to .7, and the field was more contracted than on previous occasions. The pilocarpine solution was increased in strength and the tension became normal, but the vision in the right eye did not again rise above .7. March 7, 1911, vision in the right eye still remained at .7. The field also never recovered its former size, though not markedly diminished.

In the left eye there was some congestion suggestive of chronic irido-cyclitis. Vision in the left eye by June 16, 1910, was diminished to 1/CC eccentrically.

In June, 1911, the field in the right eye had again diminished in size, but vision remained the same. The appearance of the disc was slightly more pathological in character.

In October, 1912, vision in the right eye had fallen to .5, the field had diminished, especially upward and inward, and I advised operation. The patient returned in February, 1913, and by focal light there was slight haziness of the cornea.

The trephine operation was done by me May 22, 1913. The removal of the disc left a small layer of sclera in the bottom of the trephine opening cover-

* Read before the New England Ophthalmological Society, Dec. 9, 1913.

ing the lower third. The iris was coaxed through the opening and a generous iridectomy done. There was considerable hemorrhage. Recovery was without incident. The bleb over the trephine opening was distinctly visible, though not nearly the size of the one previously described. Tension was normal.

September 13, 1913, tension was still normal and vision was 20/XL. The patient comfortable.

CASE 3. Mr. Y., 54 years of age, first seen by me November 9, 1905.

Fifteen years before he had a von Grafe operation on the left eye for cataract, and three years before vision in the left eye had begun to fail. Previously he could read fairly well.

In March, 1904, he had had a secondary operation on that eye but without benefit. When I first saw him tension was + 1 —, he saw colored rings at times, especially blue and green. The ophthalmoscope showed a white nerve with deep depression of the temporal two-thirds of the disc. There was loss of field to the inner side. Vision in the right eye was 4/CC with a partially opaque lens and no tension.

I advised preliminary iridectomy and extraction in the right eye. The extraction was done under cocaine November 19, 1905, without incident. Subsequent vision in the right eye was 20/XL. A secondary operation was done December 6, 1907. There was no ophthalmoscope abnormality of the disc.

In March, 1908, he had a hemorrhage into the vitreous of that eye which left a floating membrane. There was increase of tension afterwards and vision in the right eye fell to 7/XL. Two per cent. pilocarpine kept the tension normal and vision remained the same till January, 1910, when pilocarpine failed to control the increase of tension and one-fifth per cent. eserine was added to the solution. He had a stronger solution of eserine which he used when rings around the lights returned, that stopped the phenomenon. Vision remained approximately the same until December, 1911, when there was distinct loss of vision and contraction of the field on the nasal side.

In June, 1912, there was some steaminess of the cornea of the right eye. He was given one-half per cent. eserine to use habitually, but vision and field continued to fail and haziness of the cornea to increase. In April, 1913, after the use of eserine twice, the tonometer gave a tension of 45 mm. Hg., and I advised trephine operation.

The operation was done April 24, 1913. There was a good-sized bleb over the trephine opening after recovery. Tension was normal. By May 21, steaminess of the cornea and the little stippling of the surface had entirely disappeared and the eye was comfortable.

In September vision, which before operation had diminished to perception of light had increased to 2/C. There was no pain, tension was normal and he was using no myotic.

CASE 4. Miss R., age 59 years, first seen by me May 13, 1910.

Fifteen years before she had first symptoms of glaucoma in the right eye, *i.e.*, rainbow halos, etc. Nine years later iridectomy was done. At the time of this visit, vision in the right eye was .7 and the patient said it had remained practically the same since the operation.

Six years before she first noticed rainbow halos in the left eye, and some irritation after long use. Vision in the left eye was .7 —. She was using a myotic and was very much opposed to another operation.

Ophthalmoscope showed depression of the disc in the left eye, well marked, though not typically pathological. Anterior chamber shallow, field approximately normal. She continued under my care and with the use of a myotic, examination from time to time showed little appreciable change.

In October, 1910, the patient stated that without the use of the myotic the eye got hard. Halos were seldom seen.

September 12, 1912, vision in the left eye was .7 and the patient reported that a sleepless night, or any physical or mental disturbance would make the pupil in that eye unusually wide and that on this occasion it still remained wide open with the myotic. It was wide and one-fifth per cent. eserine was added to the pilocarpine solution. She returned three days later with small pupil. Vision, however, in September, 1912, had fallen to .5 and the field was contracted to the inner side, the tension slightly raised. It was found necessary to increase the strength of the eserine to control the situation.

In June, 1913, the patient returned after having been absent from the city during the winter. Vision in the left eye had fallen to .4 + 1. Pupil was 3 mm. in diameter, anterior chamber very shallow and there was a number of adhesions of the iris to the lens capsule. No history that the eye had been red during the interval.

I advised trephine operation and the patient consented, although she had previously determined never to have an operation on the second eye.

The operation was done June 12, 1913. The iris was so tied down that an iridectomy could not be done through the trephine opening, but a large button-hole was obtained.

November 11, the field had returned to approximately normal size. Vision was .4. No pain. Patient said the eye reddened somewhat from continued use. She was using no myotic. Tension was normal.

CASE 5. Mrs. L., 59 years of age, first seen by me September 2, 1913.

Vision had been distinctly failing for three months. Vision in each eye barely perception of light. No pain, headache or halos. Pupil not dilated, anterior somewhat shallow. Ophthalmoscope showed a large pathological depression of each disc. O. D. tension + 1 and O. S. + 1—.

The trephine operation was advised. This was done September 3d on the left eye and the 10th on the right eye.

A fair iridectomy was obtained through the trephine opening in each case and there was good drainage through the opening in each eye.

After recovery from the operation the patient returned to another city and subsequent history of the case is limited to a letter stating that the patient three months after operation could see large objects.

CASE 6. Miss L., age 73, first seen by me December 7, 1912.

First had slight discomfort and pain in right eye eight years before, and at the end of a year vision in this eye had considerably diminished until at this time there was no perception of light. This had been about the same for five or six years.

Vision in the left eye had been diminishing for

three or four years, more rapidly the past six months. There had been considerable pain, but no halos. The anterior chamber was shallow, the pupil in the left eye 3½ mm., although she was using a myopic. Tension +1 and field lost to point of fixation inward and downward. Vision 20/XXX-2. There was a deep pathological depression in each optic disc. The patient's mother lost vision in one eye wholly. Mother's brother and sister were blind from glaucoma. The maternal grandfather had very poor vision. Except in the case of the uncle and aunt, the patient did not know the cause of the loss of vision.

The pupil contracted under a myotic, the slight congestion disappeared and the tension diminished. Advised operation.

On September 10, 1913, did a trephine operation under holocaine with large button-hole iridectomy through the trephine opening. There was good drainage after the operation.

CASE 7. Mr. A., an Armenian, age 55 years.

First seen by me May 21, 1913. For thirteen months vision in the left eye had been failing, said to have followed some accident. He had an iridectomy, but the vision continued to fall. At the time of the visit, vision in each eye was falling and tension in each eye was +1. 32 mm.: Hg. O. S. and 35 mm.: Hg. O. D. Patient counted fingers at six feet with each eye.

Advised operation. Patient went away and did not return till November, 1913, and then vision was reduced to perception of motion at three feet. There was a shallow anterior chamber, pupils dilated, and the field showed that in each eye it was reduced to a small rounded area extending from the point of fixation about 25° horizontally outward, much less vertically in the right eye, and in the left eye the field of vision covered only about 10° and was similarly placed to that of the right eye.

On November 18th, a trephine operation was done on the left eye, and on November 25th, on the right eye.

The operation on the left eye was done near the margin of the previous iridectomy, but I did not succeed in increasing the iridectomy. Upon recovery there were distinct blebs over each trephine opening. On January 4, 1914, vision in the right eye was 7/CC. Tension was normal.

Any ophthalmologist who has followed these cases will recognize them as those which present the most unfavorable aspect for operative benefit, and the majority of them with the old method of iridectomy would probably go on to permanent and total loss of vision.

These operations I have done according to the method prescribed by Dr. Elliot in which a rather large flap of conjunctiva is dissected up to the margin of the cornea, thence the dissection is more carefully made so that the epithelial surface and perhaps the anterior layers of the cornea are elevated and the flap is then turned back over the cornea, the trephine blade is placed so that about half of its diameter overlaps the dark crescent of the cornea, the other half being over the opaque sclera.

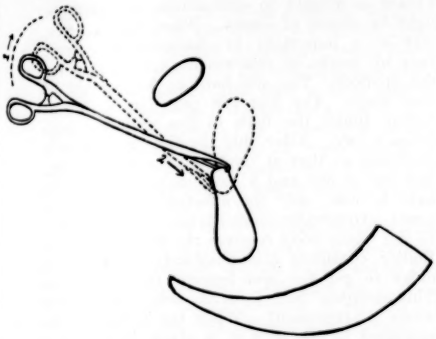
The trephine button is removed as thoroughly as may be, although Dr. Elliot himself feels satisfied if the corneal half of the opening is left patent. The iris is then seized through the opening and a portion of it removed. In most of my cases I have done a complete iridectomy. The conjunctiva is replaced and sutured.

I have found the operation in my hands easy and safe. In none of these cases did I find it necessary to use a cutting instrument to dissect up my flap from the cornea, and I did not carry the cut in the conjunctiva absolutely to the sclero-corneal margin, but I left a space of one or two mm. on each side. I have found the horizontal handle which comes with the Elliot trephine to be a distinct aid in determining the direction in which the cutting instrument is acting, as the slightest tipping of the trephine is perceptible owing to the turning of the flat horizontal handle between the fingers of the other hand. The movable stop on the blade which comes with the Elliot instrument for the purpose of guarding against too deep incision I have found to increase the difficulties of the operation by obscuring the seat of operation. However, it is of considerable comfort to the novice in this operation.

I believe we have in this method a new and valuable procedure and that its use will probably be more and more extended to other varieties of glaucoma as our confidence increases. Whether constant leakage of the fluid will tend in time to impair the physiological functions of the eye only time can determine, but as far as we can see at the present time, the trephine opening effectually prevents any subsequent pathological increase of the intraocular tension.

A SIMPLIFICATION OF THE TECHNIC OF REPOSITION OF THE RETROVERTED UTERUS.

BY JOHN T. WILLIAMS, M.D., BOSTON,



Third Assistant Visiting Surgeon for Diseases of Women, Boston City Hospital; Assistant to the Surgeons, Gynecological Department, Boston Dispensary.

THE technic usually described for the reposition of the retroverted uterus is as follows:

Grasp the cervix with volsellum forceps and draw down the uterus. With the finger in the posterior cul-de-sac, raise the fundus until it can be grasped by the fingers of the other hand on the outside of the abdomen. Then push the cervix back into the hollow of the sacrum.

This process is often very painful, and necessitates a certain amount of trauma. It has been my experience that only the first and last of these steps are necessary.

The method which I have used is as follows: Grasp the cervix with volsellum forceps, raise the handle as shown in the diagram (1), and push the cervix back into the hollow of the sacrum (2).

As the cervix is thus carried backward, if there are no adhesions, the fundus rotates forward into normal axis, upon the supravaginal attachments of the cervix as a pivot.

This procedure is more rapid and less painful than the older one and equally as effective. I have yet to succeed with the more complicated method when I have been unable to replace the uterus by the simplified procedure.

Where the uterus can be only partly raised toward normal position, not infrequently if a pessary be inserted, the uterus will be found in normal position at the end of forty-eight hours. This is contrary to the usual gynecological teaching that a pessary should never be inserted except with the uterus in normal position, but if intelligently used, the pessary can do no harm and often accomplishes what manipulation has failed to do. This use of the pessary has also been mentioned by Kelly (Medical Gynecology, New York, 1908, p. 308).

Medical Progress.

FIFTH REPORT OF PROGRESS IN ORTHOPAEDIC SURGERY.

By Robert B. Osgood, F.A.C.S.; Robert Soutter, F.A.C.S.; Hermann Bucholz, M.D.; Harry C. Low, M.D.; Murray S. Danforth, M.D.

TUBERCULOSIS.

Tubby,[1] writing in a broad general way concerning surgical tuberculosis in children and its rational method of treatment, contrasts the results obtained from the comparatively short stay of the children with bone, joint, gland, and skin tuberculosis in the city hospitals and the results obtained from their prolonged stay in the country hospitals. With the better air, the more generous sunlight, etc., the comparison leads to only one conclusion, that the treatment in the cities is not nearly as economical a method as the country method. He suggests registration and climatic treatment for all cases of surgical tuberculosis in children, outlining a broad administrative scheme and reckoning the financial needs and the approximate number of cases (one child in five thousand.) France with its large hospitals at Berck and Brevannes has shown the value of this method, and Tubby believes that the conditions in England and America demand the establishment of such hospitals in these countries also.

There has been, and will continue to be, much discussion concerning the rôle which trauma plays in the development of bone and joint tuberculosis. The study by Wilson and Rosenberger[2] therefore is of much value. They have attempted to collect the textbook and experimental evidence corroborated by cases and reach the conclusion that this evidence suggests that trauma plays an important part as a secondary cause of bone tuberculosis. There seems to be little evidence to indicate that trauma actually predisposes to bone tuberculosis in a healthy joint, but that in a joint in which there already exists disease trauma increases its activity very constantly.

Packard[3] points out the fact that the prevailing treatment of Pott's disease of the spine in jackets and braces is often unsatisfactory, and that the occasional cures without deformity are negatived by the larger number of cases which after years of disease show considerable deformity. He believes that the recumbent treatment in fresh air offers far greater advantages, and that the forces of gravity in ambulatory cases are dangerous and difficult to neutralize. The operative treatment he considers still "sub judice."

Green[4] reports ten cases of tuberculous osteomyelitis of the digits, the so-called spina ventosa. He apparently relies upon the clinical history and the x-rays for his diagnosis, and upon hygiene, local fixation, and x-rays for their treatment.

(Ed. Note: The Von Pirquet, luetin, and Wassermann reactions would doubtless help in clearing up the accurate diagnosis in this somewhat peculiar type of lesion, for the pathology of the so-called tuberculous osteomyelitis needs thorough study. It is probable that many of the cases represent mixed infections or are possibly caused by mildly pyogenic organisms in pure culture. Drainage of the bone when abscess presents has in our hands apparently been conservative of joint motion and tended toward recovery.)

De Quervain[5] believes that secondary infection is much less to be feared in tuberculous affection of the lymph nodes, tendon sheaths, muscles, or subcutaneous tissues, than in the bones and joints, and although he considers that in the former type of cases operative interference is likely to do less harm than in the latter. It is usually unnecessary when either

radio or heliotherapy can be employed. He states that 4-6 exposures to the x-rays, one every three or four weeks, each dose either a whole or a half a sabourand dose and filtered through an aluminum screen 1 mm. thick is frequently sufficient to effect a cure. He thinks that if the lesion is more than 4 cm. below the surface of the skin one can hope for little from the x-rays.

Tuberculin. We are seeing fewer favorable reports of the use of tuberculin in surgical tuberculosis. This may be because of the rather more positive results which some of the newer methods of treatment, such as heliotherapy, seem to obtain, but is also accounted for in some measure by the necessity for very careful administration which success in its use has seemed to demand.

Fenwick[6] believes strongly in its value in all surgical tuberculosis cases except those grave infections with a highly oscillating temperature. In the out-patient clinic he has administered dilutions in normal salt solution by mouth, each fluid ounce containing 1-1000, 1-100, or 1-10 mg. of tuberculin with ½% phenol. His initial dose is 1 drachm of the weakest solution or 1-8000 of a mg. and the next week he doubles the dose if there is no rise of temperature. He rarely gives above 1-100 mg. at a dose. He reports no bad results and a usual noticeable improvement in appetite, general condition, and local joint symptoms.

Cashman[7] has attempted to accurately determine the correct dosage of tuberculin. He believes that the benefit to be derived is due to the reaction of the body, not to the tolerance, and he thinks the best dose is one that produces the greatest local and focal reaction without constitutional symptoms. By using dilutions of Koch's O. T., he determines what solution is necessary to produce a skin reaction 4 mm. in diameter. This dosage used as a tuberculin injection should produce a swelling 2-5 cm. in diameter. He thus judges the proper dose for the individual case. Of 30 cases, 13 are reported well, 11 improved, and 6 doubtful.

Heliotherapy. Professor Estor[8] has described the technique of heliotherapy. The patients may with benefit rest in bed several days before beginning the treatment. As soon as the patient is acclimated the treatment may begin. At Leysin patients are placed in open galleries without glass, because the glass cuts off the violet and ultra violet rays. The sides of the terrace are shut in to protect the patient from draughts. At Arachion the sick lie flat in boats anchored near the shores or well out in the water. The head is protected with a straw hat and the eyes with smoked or colored glasses. When the temperature rises to 40° or 50° Centigrade, a light gauze is placed over the exposed parts to protect them from burns. At Leysin and on the borders of the Mediterranean all the rays of the spectrum are allowed to reach the exposed skin. On the other hand, Finsen is obliged to concentrate the northern light by means of lenses. When this is necessary it is important to eliminate the caloric rays by means of instruments constructed for the purpose. The sun bath at first should be very short. The first few days Dr. Rollier at Leysin limits the bath to five minutes, three times a day. After this the time is gradually increased so that at the end of a week it may last one or one and a half hours. At first the bath is local, only the affected part being exposed. Gradually more surface is exposed until the whole body receives the rays of the sun. Rollier considers this absolutely necessary in order to get the best benefits from the bath. This complete bath is given only after several weeks of treatment. When the patient is accustomed to the bath it is given four times a day for a period of three, four, or five hours as the time permits. Some cases are greatly benefited by five and seven hour exposures. The joints are fixed as the condition requires, and during the bath the apparatus modified to allow the greatest possible exposure. Often during the early treatment inflammatory symptoms are increased, probably by the caloric rays. This is, however, temporary. If the exposure is too prolonged there may be sun stroke and other general symptoms. The author lays stress on the fact that heliotherapy is a most valuable accessory treatment to the other well known methods.

Witek[9] reports four cases of surgical tuberculosis treated by heliotherapy with an ideal functional and anatomical result, and Alkan[10] has demonstrated that even in the city by placing the children on the roofs or high balconies much may be accomplished by the direct sunlight treatment.

D'Oelsnitz[11] also believes that we must place heliotherapy in the first rank of anti-tubercular measures, but mentions certain untoward effects which have been occasionally observed. For example, that there may be local aggravation of symptoms, usually temporary, but occasionally persisting, and accompanied by loss of weight. In lung cases and in visceral cases hemorrhages sometimes occur, and excessive heliotherapy has been followed by meningeal symptoms. Certain observers, as Vulpius,[12] consider the technique as still incompletely worked out, and are unconvinced that altitude is as important a matter as has been believed. It is remarkable, however, that there seems to be such a consensus of opinion as to the value of the method. Light therapy as well as fresh air and good food therapy would seem to have its individual permanent importance. Since natural sunlight cannot constantly be had and altitude and long days are not within the reach of all, many attempts have been made and are still being made, to artificially produce light rays exactly similar to the beneficial rays of the sun.

Hagemann[13] believes he has produced light

which may fairly be called artificial sunlight, and is superior to the ordinary artificial lights, such as those derived from the Friesen-Beyer, the mercury vapor, and the quartz lamps, which according to Rollier give only a local and an inefficient radiation. Hagemann's device is a quartz lamp surrounded by a corona of simple electric lights. He reports 52 cases treated by this method, with an unusual and satisfactory gain in weight, appetite, longer hours of sleep, and a disappearance of pain.

A very comprehensive volume dealing with the technique of application and the effects produced by the various medical quartz lamps has been written by Meuser,[14] bringing up to date this method of therapy, which is apparently winning many converts, especially in Europe.

ARTHRITIS.

More positive evidence of the infectious nature of rheumatism is furnished by the work of Beattie and Yates,[15] who seem to have been more fortunate than most investigators in establishing a causal relation between the streptococci which they isolate from knee joints and tonsils in rheumatic patients and the arthritis. They have isolated an organism in 129 cases and have inoculated 41 animals. In 9 cases where a definite arthritis existed they have produced a pure arthritis in rabbits in 8. In certain cases where there was no rheumatic history and in certain tonsillar cases the isolated organism produced a septicaemia in nearly every case, sometimes accompanied by an arthritis. The discovery of the organism in the blood is always difficult, but in 3 of 11 rheumatic cases they have succeeded in isolating an organism which produced a pure arthritis in rabbits. They believe that the focus of infection is in the throat or alimentary tract.

Gudzent[16] has examined the blood of 100 patients with "chronic articular rheumatism" with special reference to the number of lymphocytes. Normally the lymphocytes comprise about 20-25% of the white corpuscles, but in these cases the percentage was noticeably increased, being normal in only nine patients, 25-30% in 19, 30-40% in 42, 40-50% in 24, and over 50% in 8. The mononuclear and eosinophilic forms showed no change from the normal percentages and the number of red blood corpuscles and the amount of haemoglobin was normal. Gudzent offers no explanation, but calls attention to the fact that frequently a decrease in the number of lymphocytes has been observed in tuberculosis.

Bornstein and Plate[17] have noticed that a chronic arthritis not infrequently occurs in persons obliged to work under compressed air. They believe that this occupational disease may to some extent be guarded against by gradually accustoming the subject to the usual conditions of life and by insisting upon the slow passage from rooms where compressed air is breathed to the ordinary air.

Lipoma and Synovial Fringes of the Knee. Lefevre and Dubourg,[18] after a review of some seventy-seven articles reporting cases of hypertrophy of the synovial fringes of the knee, consider the main points of diagnosis to be the following. (a). The long duration of the affection and the remarkable contrast between the relative freedom of movement and the changes in the shape of the joint; (b) the contrast between the frequency and intensity of the pains when the knee is used and their rapid subsidence during repose; (c) the integrity of the bone and cartilage forming the joint and the peculiar palpation findings. In short, the first thing when one considers the possibility of lipoma is to appreciate the contrast between the appearance and palpation findings and the practically unimpaired functioning of the joint. They think that conservative measures are futile, and advise partial or total synovectomy, leaving the bones and cartilages intact. As a rule, the patients recover without impairment of function as soon as the excrescences have been removed from the synovial membrane. The authors believe that the three affections, arborescent lipomata, villous polyarthritis, and "Hoffa's disease" are merely three forms of a single lesion which may be termed chronic, polypiform, fibroadipose synovitis.

(Ed. Note: We agree that the large solitary lipomata which give rise to symptoms and the chronic fibrous villi, which are frequently pinched and give sensations of catching, should be removed by operation. Formerly we believed that most cases of villous arthritis should be operated upon, but a thorough trial of the more conservative measures of diet, strapping with adhesive plaster protection of the anterior capsule by apparatus, and the various thermo- and hydrotherapeutic measures, has demonstrated the fact that many of these cases apparently entirely recover without operation. We believe, therefore, that except in those conditions mentioned above, conservative measures should be given a fair trial before the synovectomies advised by these authors are undertaken. We have seen impaired joints and recurrence of symptoms after these radical operations.)

Lasserre[19] reports that the treatment of gonorrhoeal arthritus with anti-meningococcus serum has been very successful in France. It seems peculiarly effectual in the subacute form with a tendency to septicaemia and in the acute types with a tendency to ankylosis. The chronic forms rebellious to other measures have in his experience been favorably modified by it. Lasserre states that four or five injections in 0.2 or 0.3 mg. every four or five days are generally sufficient.

Wolf[20] has been impressed with the beneficial effect of early massage in even the acute gonorrhoeal joints. He believes that careful and in-

telligent massage may be begun about two weeks after the beginning of the disease and its effect is to relieve rather than increase the acute sensitiveness. He gives the credit for this procedure to Bauer of Bergmann's clinic, who considered this treatment safe because of the fact that gonococci in the tissues are very short lived and the chances of causing other infectious processes are very remote.

Handley and Ball[21] claim priority (Jan., 1913) for an operation on hypertrophic or osteoarthritic hip joints which they call "cheilotomy." This operation consists in removing the overgrowth of bone about the acetabulum and restoring free motion in rotation and abduction. Their two cases were in men aged 56 and 62, and they state that they were of traumatic origin. They used a posterior incision and chiselled off all of the "lip" but do not carefully describe this difficult procedure. The results were good four months later.

(Ed. Note: We mention this report because this is an operation which has been done in America in specially selected cases for many years. In the purely traumatic and seemingly quiescent hypertrophic arthritic cases after a trial of complete fixation, it has been useful in gaining more motion and relieving pain, but it should be borne in mind that in many of these cases the limitation of motion and the pain are not caused by the overgrowth of true bone evident in the x-ray, but by the osteoid tissue and general joint sensitiveness which may disappear under fixation. We have been able to relieve by plaster or leather spicas, certainly for years, several of these cases in which the x-ray showed a definite overgrowth, and in which the limitation of motion was marked. The freer motion has persisted after the removal of the fixation unless the underlying disease became active again or trauma again entered in. The operation in the elderly is not without shock, and to reach all the overgrowths may in unskilled hands easily result in greater crippling than the disease. These overgrowths about the hip joints are seen very frequently and we do not believe that this operation should in any sense be considered a routine procedure. It is fair to say that the authors themselves do not advise it in active cases or where other joints are involved.)

POLIOMYELITIS.

An unusually severe epidemic of poliomyelitis in the Parish of Morehouse, in Southern California, has been reported by Patterson[22] in the *New Orleans Medical Journal*. There were 60 cases in six months, and there was a 25% mortality, most of the cases being very acute.

Fraser[23] has examined the cerebro spinal fluid in 126 cases of acute poliomyelitis with the purpose of determining the value of the examination as an aid to early diagnosis and as an indication of the severity of the disease and its probable course. He finds the fluid usually clear, colorless, and under little pressure. In most of the early cases there was some increase in the mononuclear cells, chiefly of the lymphocytic variety. He concludes that while the examination may be of value in the preparalytic and abortive cases for purposes of diagnosis, it has no value as a prognostic sign.

Rosenau[24] discusses the report of the work of the Massachusetts State Board of Health, which seems to indicate that the stable fly is the principal agent in the transmission of the disease. Sawyer and Herman[25] were able to transmit the disease from monkey to monkey in seven cases by means of the stable fly. They, however, doubt that this is the usual mode of transmission and maintain that every precaution against contact infection should be taken.

Allison[26] writing concerning the results obtained by the implantation of silk tendons, after much experimental work on dogs and clinical experience in human beings, reaches the conclusion that in the severer forms of poliomyelitis in children this is a valuable method and that the results are better than in operations where there is removal of bone.

Bartow and Plummer[27] also report excellent results from their later observations of the use of intra-articular silk ligaments in paralytic joints of poliomyelitis. These operations have been devised by them as well as performed, and they report 50 cases without any infection or any tendency for the Lange paraffined silk to cut out or act unfavorably as a foreign body. They consider that the developmental stage of the operation has been passed and that it should be more generally adopted.

(Ed. Note: The editors have observed a comparatively small number of cases treated by these intraarticular silk ligaments. These cases have been distinctly improved and the silk has remained in and performed its function.)

SPASTIC PARAPLEGIA.

Gaugele and Gumbel[28] have published a volume on Little's Disease, the main object of which is to answer the question as to whether Foerster's operation has fulfilled its expectations. They do not think it has. They base their conclusions on the examination of many children at the Home for Crippled Children in Zwickau, some of whom have had Foerster's operation performed upon them and some of whom have been treated by the simpler orthopaedic methods. They think the condition of the latter class compares favorably with the condition of the cases in which division of the posterior nerve roots has been done.

Biesalski[29] also discusses the theories of the causation and methods of treatment of spastic paralysis, and while reporting excellent results from Foerster's operation and the nerve resections of Stoffel, he considers that the thorough and correct application of exercise treatment

and muscle training is the most valuable method of treatment. *(To be continued.)*

Reports of Societies.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

THIRTIETH ANNUAL MEETING HELD AT WASHINGTON, D.C., MAY 6, 7, 8, 1913.

(Concluded from page 359.)

DR. E. FLETCHER INGALS, Chicago, read an article entitled,

WHAT RELATION, IF ANY, HAVE THE TONSILS TO PULMONARY TUBERCULOSIS?*

During the last fifteen years many articles have appeared in medical journals on the relations of the tonsils to pulmonary tuberculosis. At the early part of this period, it was frequently claimed that the tonsils were a common portal of infection for the pulmonary disease, but subsequent research demonstrated that the tubercle bacilli might penetrate the tonsils and pass through them to the lymphatic cervical glands, causing tuberculosis of the latter, without any involvement of the faucial tonsils. It was shown, however, that there was no connection between the cervical glands and the pulmonary lymphatics. In a small percentage of cases the tonsils appear to be primarily involved in cases of pulmonary tuberculosis, but usually tubercular changes in these glands are secondary and the bacilli appear to have been absorbed from the sputum. It has been shown that the tonsils are the portal of entrance for the tubercle bacilli in many cases of tubercular cervical adenitis, yet inflammation of the cervical glands, non-tubercular in character, appears to be much more frequently due to absorption of infection through the tonsils. The consensus of opinion now is that pulmonary tuberculosis is generally a systemic infection of aerogenous origin, and that when the tubercle bacilli are taken up by the lymphatics they are poured into the general circulation. In pulmonary tuberculosis the bronchial glands may be primarily involved, but this does not appear to be the usual course of the disease. In a recent statement one of the best known pathologists says that he does not think there is any relation between diseases of the tonsils and pulmonary tuberculosis.

DR. W. E. CASSELBERRY, Chicago: The accessory nasal sinuses are such exceedingly complex structures and so intricate of access that one or more small sinuses may escape our attention; even knowing where they may be involved we find our access at fault. Rhinologists have been preaching a nasal origin for asthma and the nasal cure for asthma, and it has never been accepted by the medical profession for the reason that its explanation was not lucid. That these swellings in the antrum which we used to say were congestions, are secondary to nasal accessory sinus suppuration, which in turn occasions the asthma through toxemia by absorption of pus.

* This article appears in full in the *Journal of the Amer. Med. Asso.*, July 12, 1913.

DR. BROWNING, Los Angeles: I recall one case where a patient had been operated on for chronic appendicitis and afterwards the asthma was much relieved. I have had two cases within the past three years of tuberculous glands, one in a child and the other in an adult, who were treated for the tuberculous condition by the administration of tuberculin, and the asthmatic condition has disappeared and so far has not returned.

DR. R. H. BABCOCK, Chicago: We cannot expect patients to be cured if the surgeon merely removed the polypi. One case I recall was a woman who had a local polypus in the nose. The mere removal of nasal polypi is not sufficient, and the reason why this procedure has been followed by only partial or temporary relief lies in the failure of the operator to recognize or remove the hyperplastic ethmoid responsible for the polypi. The effect, we all know, of whiskey on asthma. I think all the facts point to asthma as a phenomenon of anaphylaxis, and I think this view is going to lead to the cure of many cases since asthma has been a distinct reproach to the medical profession.

DR. THOMAS W. HASTINGS, of New York, presented a paper on,

THE RECIPROCAL RELATIONS OF THE CLINIC AND LABORATORY IN MEDICINE.

The author considered the indebtedness of the modern medical clinic to the medical sciences; most clinicians in the rank and file of practitioners deny that there are diseases in which laboratory knowledge counts for everything and that experience of thirty years develops not so much proficiency along certain lines on the first as the modern first grade medical school imparts to its latest graduates.

DR. HASTINGS took up the evolution of epidemiology, the discovery of "carriers"; the indifference to autopsies of most physicians; the complacency with which most diagnoses are made; the advancement of laboratory trained men to clinical positions. Professors in medical colleges should be men who know considerably more of the subject they teach than the clinically trained men in medical schools can ever hope to know on account of the little time the active clinical man can give to keeping pace with any medical science.

DR. E. K. BALDWIN, of Saranac Lake, read a paper on,

THE FRUITS OF LABORATORY WORK IN RELATION TO CLINICAL TUBERCULOSIS.

Much that has been learned empirically about the treatment has simply been confirmed by the laboratory, but it has given us more delicate indications, more definite means of control. Foolish or injurious therapy has been discarded in consequence of tests made in the laboratory. Theories have been born and have died in the laboratory. Too many bedside ideas have been born of criminal ignorance that tuberculosis is a deep-seated infection, that cannot be reached by medicaments as harmful to the tissues as to the bacillus. The public has been led to expect that all the ills of human flesh can be cured by some serum evolved out of a laboratory. Let us do our best to give them a saner view than this without discrediting the real good that comes from it.

DISCUSSION.

DR. CASSELBERRY: I must say it never occurred to me that the laboratory needed any defense. I think its justification can be summed up in two words, antitoxin and Wassermann.

DR. A. K. STONE, Boston: There is no laboratory procedure that cannot be called in question. Even the almost indisputable bacillus of tuberculosis may be disputed, for there are other acid-fast bacilli that come in at times. Nothing gives a man more pleasure than to have enough laboratory knowledge to be able to check up laboratory findings for himself; and even if he cannot go ahead and make new examinations and discoveries, he can have lots of fun in the laboratory.

DR. MINOR: It is an impossibility in these days for a man to be a laboratory man and a clinical worker in a very large practice. The demands of the laboratory upon his time are insistent and have to be met; the demands of the patient are insistent and have to be met, and the two cannot to any great extent be combined. My complaint is that, for reasons that cannot be easily explained, there is a distinct arrogance in the attitude of the modern laboratory man toward the clinical worker. He has done great things; it was the result of the laboratory work that gave us diphtheria antitoxin, and a great many things, and I would not belittle it for a moment; but I cannot admit their claim to the exalted position that they would arrogate to themselves. They must come second to the clinician. We all admit that the plain clinical worker has done in the past and can still do excellent work for sick people without the laboratory, while the laboratory man is perfectly unable to do anything without the clinician. Now my contention is that he thinks he is not secondary, but primary. It was for that reason that I asked a typical laboratory worker like Dr. Baldwin, who combines the clinical and laboratory methods in a happy way, to prepare this paper. I feel in the long run that a balance will be restored. The final effort in medicine is therapeutical, and medicine which does not result in therapeutics is useless, and the world would reject medicine tomorrow unless these resulted in the good of the patient.

DR. POTTENGER: The reason why a clinician, as a rule, cannot do efficient laboratory work is because these two lines of work are adapted to an entirely different type of mind. The clinician is essentially an optimist, and he should be. He sees the needs of his patients and furnishes them. The laboratory man is slow, patient, and ultra-critical in his work. I believe it is absolutely impossible for a clinician working hard all day to sit down and patiently work out a laboratory problem. I have observed that most men who undertake both clinical and laboratory work as a rule neglect one or the other.

The laboratory man is apt to believe that his work is exact. It is not. We clinicians know that our clinical work is not exact. He also is not exact; there is just as much error in the laboratory as there is in the clinic. Now if we learn this fact, if we learn that the laboratory is our greatest helpmate, if we use it right, and learn that it is not as exact as we have been thinking, then, and not till then, will the laboratory and the clinical man be on their proper basis.

DR. KINGHORN: Dr. Pottenger said that the two could not work together, that is to say, a man cannot work in the laboratory and in clinical medicine. Now the physician that I recognize today as being the first physician in the land for what he has done both clinically and in the laboratory, belongs to this society, Dr. Trudeau. As you know, he is a great clinician. There is no one, I think, who can equal him in his clinical knowledge of tuberculosis. No one also can question the rank that he has attained as a laboratory worker in tuberculosis. In other words, he has combined in himself a great clinician and a great laboratory worker. I can also refer to his first assistant, the vice dean of our school up in Saranac Lake, whom I have often thought of as the Elisha, and who is the writer of this paper; and Dr. Baldwin certainly has combined those two qualities. He is a clinician of world-wide renown, and he is also a laboratory worker of world-wide renown, so that I think it shows that these two qualities can be combined in one man. Now, of my observation of the trend of medicine in late years, it is that the physician has combined clinical study with laboratory study. For instance, the Rockefeller Institute was started primarily for investigation. What have they done? They have their Institute right alongside their hospital, so that the two can be combined right there. The whole trend of medicine today, I think, is to combine the two. Dr. Minor has said that a man with a large practice cannot do both. I say that in order to meet that condition, do not let a man have such a large practice. There are other men that are coming along that need the help, and let them share the practice. I am sure, because I have combined laboratory work with clinical work; and I know that you get great principles of treatment from the laboratory that you would not get by reading, and that you will only get them by the laboratory, and I say the whole trend of medicine today is to combine clinical and laboratory study.

DR. POTTENGER: I still maintain that these are the exceptions, and not the rule. I think we all recognize that Drs. Trudeau, Baldwin and Kinghorn are exceptions in their work, but that does not prove that it can be done generally. I could not do it.

DR. BALDWIN: You all agree with me that the well-rounded man has to know something about laboratory work, although he cannot do very much. As for Saranac Lake, this mutual admiration society which Dr. Kinghorn has started up leaves me no answer. In regard to the man who is doing so much practice that he cannot keep up with the laboratory work, I think Dr. Kinghorn's contention is correct. No man should feel himself so desirable to his patients that he cannot take help. He can turn his patients over to somebody else, and the only way that you can comprehend the field of medicine,—and I may say the field of tuberculosis today,—is to have plenty of help, and I mean by that, help in the practice of medicine; and if you are going to keep up even with the new things that are coming up all the time, a man has to be well-read. Then another thing, a little laboratory experience makes a man more self-critical. I do not say it makes him any better practitioner; I think sometimes it interferes with his being a good practitioner, simply because he does not give his patients so much hocus-pocus,—so much talk! But after all, the patients get more confidence if they live long enough with him. A man who is doing both ought to be theoretically better rounded. I have had plenty of experience in both ways, and I realize

my deficiencies in the laboratory work, and I also realize the tremendous advantage that it has given me, and I speak of it modestly because I realize so many mistakes that I have made in clinical work, too. Do not expect such accuracy in the laboratory that you need to consider that as the final word.

DR. JAMES M. ANDERS, Philadelphia, read a paper on,

THE RÔLE OF PHYSICAL EXERCISE IN THE OPEN AIR IN THE PROPHYLAXIS OF TUBERCULOSIS.

There is a disposition on the part of physicians to overlook the importance of muscular exercise in the prophylactic treatment of pulmonary tuberculosis, since the general acceptance of the principle of rest in the treatment of all cases of this disease in which fever is present. The object of this paper is not to attempt to underrate the great value of rest in the active stages of this disease, but rather to emphasize the first-rate importance of the systematic muscular exercise as a means of minimizing the number of susceptible persons.

The American race, as a whole, is undergoing muscular deterioration. On the other hand, the endurance or resistance of an individual is in direct relation to his muscular development. Muscular development was considered in relation to climate. The prevention of tuberculosis involves something more than physical exercise, but the commanding position of this measure is undoubted. The effect of systematic physical exercise, combined with deep breathing, upon the vital power and resistance of the lung texture was considered. Competitive athletics is not to be encouraged among the young. Increased respiratory exchange in muscular activity increases the nutrition and general health of the body. The details connected with the question of the regulation of muscular exercise must vary with the individual.

DR. A. K. STONE, Boston: In the schools there has been a marked change for the better in the matter of fresh air. In Boston there is a general rule that between each lesson period the windows shall be opened while the class does gymnastic and breathing exercises and also again at recess and before the sessions. This rule is at present much modified by many ancient and thin-blooded teachers. At present in Boston we are preaching the open-air school room gospel by an illustrated lecture at the moving picture houses, thus reaching many thousands of mothers and children. The department stores are making provision for rest and exercise as well as for the proper feeding of employees,—all under the most favorable conditions of fresh air.

DISCUSSION.

DR. E. O. OTIS, Boston: In the stress and strain of life it is often difficult to persuade men to take time for physical exercise out of doors. The two classes of people who need it most are the students in school and college and the older men who are retiring from more active duties. Physical exercise should be followed by rest, and not taken when exhausted, but when a certain amount of vigor remains. If men cannot take time for outdoor exercise, carefully supervised and directed physical exercise of the gymnasium will accomplish excellent results. Where you have a limited time, the degree of efficiency by which the various exercises can be applied by a successful director in the gymnasium would accomplish a very great deal.

DR. W. H. SWAN: I was very glad to see the distinction drawn between the value of physical exercise, and the overtrained college athlete. I have seen a considerable number of men who in college had been on football teams and boat crews and had afterwards broken down with tuberculosis, and I have the distinct impression that they do badly. I am sure I have not seen one man who was on the college team, and was thoroughly trained, as I believe they are trained, who has afterwards done well when he had tuberculosis. In line with Dr. Otis' statement regarding rest after exercise, I think that is extremely important, and also the question of not exercising when the person is mentally fatigued. I believe that our tank of energy is all one and if we drain it by mental fatigue and nervous fatigue we have not any left for physical exercise. I think that if the person is very tired mentally he will get no good, but harm out of it.

DR. C. H. MINER: We must also consider the value of rest and exercise in children. In trying to build up children of tuberculous parents in a dispensary where we take tubercular parents, we have the nurses bring all the children to the dispensary for examination. The children from 5 to 14 years of age are usually in perpetual motion when they are not asleep, and it is difficult to secure any improvement in them. The preliminary part of the treatment is physical rest; that is the most difficult part of the treatment to secure. Then, in later life, when the young adults and youths should be having physical exercise, they are in school and not taking necessary exercise that would develop their chest and keep them in good physical condition. We must not urge physical exercise on young children.

DR. ALTON: I want to make one brief comment on the matter of pulmonary exercise or pulmonary athletics. Lung expansion is an exceedingly important thing to consider in those cases that we call pre-tubercular, with no evidence but the diminished vitality of the patient to lead us to fear something to come. There is a large class of men, usually from 20 to 35, in stores as clerks. These men have a low resistance power. We take their chest measure and find a difference of perhaps only an inch and a half between expiration and inspiration. They do not know how to expand their lungs. There is one simple method that I have not infrequently advised in cases where I feared that the slight pulmonary expansion might lead to trouble later on, that is pulmonary gymnastics as an evening exercise. The patient starts out before going to bed, walks half a block, then stands and fills his lungs as full as possible, walks a little further, and then the air is expired. This is repeated several times. These are the cases we cannot send into the mountains to walk up hill to get the same result, but they can get it at home, late in the evening after they have rested from the fatigue of the day, and just before going to bed. I think if any one would follow this method in a given number of cases he would be surprised at the beneficial result.

DR. JAY PERKINS, Providence: I appreciate what Dr. Miner and Dr. Swan have said in regard to the rest of children from tuberculous parents, and those who are fatigued with mental work, and I agree fully with them. I think that in our fresh-air schools one of the advantages we have is the exercise that is given these children, and I believe in

all of our schools there should be a period of intermission and exercise. Part of the benefit is because the children are mentally fatigued. It does give their minds a rest; they can work better afterwards; they can do far better mental work after exercise, as I myself have experienced many times; and I think the most of us have felt better when we have taken a 15 or 20 minutes brisk walk after a hard afternoon in the office.

DR. ANDERS: As to what Dr. Otis has said with reference to the difficulties in carrying out physical exercise among the clerks, and business men as a class. On the other hand, it is possible to give them such direction as they can and will follow, and secure a fair amount of muscular exercise. My own method is to request such patients to walk to their work; if it be too far, then a portion of the distance only. I often tell them to leave the trolley car or other conveyance when within ten blocks or a mile of their offices, and to walk to their destinations very briskly; likewise again at the noon hour. Mornings and nights they must be taught to practice calisthenics for five minutes, and if carried on systematically, this proves most useful. Of course exercise must be alternated with rest. That this work should and eventually must begin among the children in our public schools is undoubted. As compared with the amount of attention given to mental training, surely that bestowed upon physical training is far, far, too little. We want, if possible, to create public sentiment in favor of more and better graded physical education; less pushing of the mind at the expense of the sinews and muscles.

DR. WM. CHARLES WHITE, Pittsburgh, read a paper on,

THE INFLUENCE OF HEAVY SMOKE ON ACUTE AND CHRONIC LUNG INFECTIONS.

Smoke as a problem of cities' health has its main influence upon the respiratory passages. As types of acute and chronic lung infections, on which smoke may have a varying influence, pneumonia and tuberculosis have been chosen. These diseases have been studied from a statistical standpoint for various cities scattered throughout the United States, and comparisons made with the city of Pittsburgh, which probably has the greatest number of smoky days in the year.

In considering the influence of smoke on acute and chronic fatal lung infections, the question of age of distribution, age of city, poverty on the basis of congestion; and topography of the city have been taken into account. The latter feature in such a city as Pittsburgh, with high hills and river valleys, allows a partial segregation of the city into areas of varying smoke density. In other cities, such as Indianapolis, the flat contour does not allow such divisions.

The chief tendency of the study seems to indicate that smoke has rather a severe influence on pneumonia, with a much less influence on tuberculosis.

DR. POTTENGER: Several years ago when traveling through Europe, a layman asked me the question, why it was that the coal miners in Westphalia did not have tuberculosis, and he said that it was true that there was very little of it.

According to Dr. White's chart, Los Angeles has a high death-rate and very little smoke, but everybody knows that the death-rate is high from the fact that a large per cent. of our tuberculosis patients die within the first year because they come into Los Angeles to die.

DR. CASSELBERRY: So many things contribute to the causation of tuberculosis, the density of population, housing and working conditions, sunshine, winds, and dust aside from the carbon of smoke, that it does not seem likely that a chart based alone on carbon contamination can be reliable. We ascribe some of the bad results of the associated gases and other vitiating substances, such as carburetted hydrogen and sulphuretted hydrogen.

DR. BROWNING: It would seem to me that in the open tuberculosis resorts, some effort should be made to segregate the persons who die in these resorts into those who have recently become residents and those who have been a longer resident. I think this would not be very difficult with reference to Los Angeles. What Dr. Pottenger has said may seem as a joke, but it is a fact. Not only about what he said about half of the patients dying within the first year of residence, but about one-fourth during the first month, so you see that the climatic condition of Los Angeles with reference to any local condition, has no effect upon that class of cases. I take the same to be true of any other open resort. It would be very little effort, I think, for the state board of health or the city health authorities to segregate them.

DR. LINSLY WILLIAMS: As to the death-rate from tuberculosis in the different cities, it always seemed to me quite necessary that the cities, if possible, should afford a corrected death-rate, but I do not see quite how they can figure it out if cases are reported as tuberculous, and then are lost track of by removal; and it is difficult to trace them. It may be that one of the reasons why the death-rate is diminished in the cities is because the patients are leaving the cities.

DR. ANDERS: I was much surprised to learn that the influence of smoke on the incidence of pneumonia was greater than on that of tuberculosis. It is quite possible that Dr. White's explanation of this discrepancy is entirely correct. I think it is almost an invariable rule that a person suffering from advanced anthracosis, coming from the coal regions of Pennsylvania to our hospitals in Philadelphia, finally develops pulmonary tuberculosis, which is apt to pursue the usual course of this disease. It is possible that the implantation and the progress of the disease may be retarded in the manner explained by Dr. White. Dr. White chose wisely when he selected pneumonia and pulmonary tuberculosis as types of diseases for comparison, and I think we must allow that his tentative conclusions have more than ordinary value in view of the fact that he has taken into account a great many interfering conditions, *e.g.* the topography, the local congestion of the population, etc. He said nothing about dust in his remarks. Not wishing to criticize his paper, I still think that this and other associated impurities might have been considered in this connection. Truly Pittsburgh, owing to its peculiar topography and the fact that it is the smoky city of our country, is a very fertile and appropriate field for investigating this subject, and I certainly trust that Dr. White will continue his work in this line because it will require observation over a long period of years to give us reliable results.

DR. HINSDALE: I have always understood that one of the deleterious influences of smoke was the fact that it contained so much sulphuric acid; and there are many interesting calculations about the

number of tons of sulphuric acid which are deposited each day in a large city like London from the various furnaces and fire-places in that city, so that the carbon particles being associated with free sulphuric acid, and being inhaled into the lungs is a very bad combination, of course. It would take a long time to convince me that carbon particles, even free from sulphuric acid, if such were the case, would not do the lungs any harm, or would not incite, probably, the infection of tuberculosis.

DR. DELANCEY ROCHESTER, of Buffalo, read a paper on,

THE TWO MOST IMPORTANT FACTORS IN THE PREVENTION OF TUBERCULOSIS.

The detection and destruction of tuberculous cattle will, of course, eliminate the extension of the bovine form of tuberculosis to the human race and the passage and enforcement of laws to this effect should be persistently urged. In this way one of the two great factors in prevention will be made effective. The compulsory segregation of patients in advanced stages of pulmonary tuberculosis was urged. Every case should be investigated, and if unwilling or unable to properly care for himself at home, he should be committed to a sanatorium, for incipient or advanced cases, to stay there until cured or dead. Cremation was urged in case of all deaths from tuberculosis. Instruction in regard to destruction of sputum and feces, in regard to precaution as to personal contact with others and in regard to disinfection of apartments lately occupied by the tuberculous are all of value in checking the spread of the disease; but the author believes strongly in compulsory reports of cases and compulsory removal of suitable patients to their proper sanatoriums.

DR. MINER: The criminal and ignorant poor are absolutely unable to handle in any way their own cases. The advanced tuberculous patients with bad habits are a great source of spread of the disease. It is hopeless to expect these criminal and ignorant poor to be benefited by the ordinary treatment. They will go home and repeat the same errors, and they will serve as sources of infection. I think we have just as much right to segregate them under police control as in smallpox and other contagious diseases. This is important, and until those patients are treated in that way a large part of our efforts toward eradication of tuberculosis is entirely wasted.

DR. OTIS: I want to ask if I am not correct that the human tubercle bacillus will live only at a temperature of 37° C.?

DR. W. L. DUNN: I had an interesting experience recently that I think will perhaps be worth while relating even if it is out of order. Some years ago I had occasion to set aside some cultures. The culture was implanted in March, 1907. Four weeks ago I found that culture, and I thought I would simply see whether it was still alive or not, and that culture grows with facility; it is one of the most rapidly growing cultures.

DR. BALDWIN: I think these statements will only illustrate, as was said here previously, that laboratory results are sometimes fallacious. It has been proved that these earthworm bacilli are not true tubercle bacilli. It is known that they are saprophytic bacilli that grow at cold-blooded temperature and the earthworms are not of any danger to the human being. The turtle bacillus is exactly the same kind.

DR. ROCHESTER: Dr. Otis asked why I said that the bodies of people who died with tuberculosis should be cremated. I feel that all bodies should be cremated any way, but that is another question. The reason I said this in regard to tuberculosis is that tubercle bacilli have been demonstrated in the bodies of earthworms, and it is possible that we may have a spreading of tuberculosis through plants, through lettuce or some other food which may be eaten. It is a mere possibility, but it is a possibility to consider. I thoroughly believe in cremation. There is one other view on which I wish to very decidedly express myself, in regard to the detention ward. I am very glad to hear that they have already established a detention ward in Cincinnati. We are about to try it in Buffalo. I have in mind just one case which illustrates the seriousness of letting patients out to go home to die. I treated a man in advanced tuberculosis some years ago, who finally went home to die. He had a wife and five children. Four of these children and the wife have since died of tuberculosis. He went home to die and they died too.

DR. CLEAVELAND FLOYD, of Boston, read a paper on,

ARTIFICIAL PNEUMOTHORAX IN THE TREATMENT OF CHRONIC INFECTIONS OF THE PLEURA AND LUNGS.

The author has treated during the past four years a fairly large number of cases of pulmonary tuberculosis by nitrogen compression. Some of these have been under treatment primarily for one or more symptoms, such as cough or hemoptysis; but in the majority the object was to arrest an advanced active process. In the larger number reduction in temperature, relief of cough, diminution of expectoration and increase in body weight have occurred. Improvement in circulation, gain in weight and increase in strength followed even where the extent of pneumothorax was limited. In cases of mixed pulmonary infection results have been fairly good only where collapse of the lung has been extensive. The compression of a portion of the lung tends merely to diminish the amount of sputum and reduce temperature. The action of pyogenic organisms is not checked and lung destruction slowly advances. In unilateral cases of active tuberculosis, not only relief of symptoms but arrest of the disease has been obtained. Occasionally it has been possible to arrest the disease in one half of the chest and later, after allowing this lung to re-expand, to compress the second, which has shown evidence of activity. Such cases are reported by German observers. Dr. Floyd exhibited the apparatus used for making the nitrogen injections and described the technic.

DR. HARRY LEE BARNES AND DR. FRANK TAYLOR FULTON of Rhode Island read a report of

SEVENTEEN CASES OF PULMONARY TUBERCULOSIS TREATED BY ARTIFICIAL PNEUMOTHORAX.

(See the JOURNAL, June 19, 1913.)

DISCUSSION.

DR. E. O. OTIS: Boston. I have had occasion to observe this operation recently in Europe. There is a diversity of opinion in regard to what the pleural shock really is. Many authorities attribute it to gas embolism. This is a great danger, and to minimize this danger Prof. Deneke of St. George's Hospital, Hamburg, has devised an apparatus which is

the best for the purpose of all those I saw in Europe. Prof. Deneke's idea is that greater safety is insured in the first injection by using oxygen gas, which is more readily absorbed and is less likely to produce gas embolism should the needle enter a vessel. By simply turning a stopcock he turns to the nitrogen apparatus and injects nitrogen. At my suggestion one of the instrument makers in Boston has imported this apparatus. In every instance the operators in Europe insist upon a very careful x-ray. The Forlanini method was generally adopted, and only in one clinic I saw the open operation used.

DR. W. H. SWAN: Is there any advantage in the nitrogen gas as compared with air, other than it being absorbed less readily, and how much less readily is it absorbed?

DR. W. A. GRIFFIN, Sharon: We have had a series of cases, about as large a number as Dr. Barnes has reported, and we feel every confidence that the majority have been much benefited by the treatment and in perhaps two or three instances we feel that the patients have been brought back from a very perilous position. The most striking case was not, strictly speaking, advanced. The patient had slight signs of tuberculosis of the left lung, with a constant temperature, and it was because of this constant temperature that pneumothorax was finally induced. I think it is important to determine the indication for renewed injections in any case under treatment. What guides have we to go by? The cough is a very decided indication; if it commences to increase that is time to consider another injection; if the amount of sputum commences to increase that is another sign, and if the needle upon being introduced shows a marked negative pressure, that is, perhaps, the most sure and definite sign.

DR. JAMES ALEXANDER MILLER, New York: The experience which I have had in 25 cases convinces me that the percentage of far advanced cases in which you can get very marked results is limited certainly to not more than 10%; but we have had very good results in cases not advanced, but where they had hemorrhages, that frequently being the first symptom, and I have treated since such cases with remarkable success. In three of them they had been bleeding from a pint to a quart a day, and with rising temperature, with no evidence of ceasing of hemorrhage. After the injection of gas the hemorrhage stopped and prompt reduction of fever resulted. We have in such cases as that an indication for prompt pneumothorax treatment. Whether it should be continued or not after the hemorrhage is controlled should be decided for each individual case. In these chronic, advanced cases you get hung up and you are afraid to stop and really feel that it is not justifiable to keep on. We expect to use it in more acute cases with hemorrhage, and also the acute febrile cases with limited lesions.

DR. MILLER related a case in which the nitrogen was given after careful local anesthesia with novocaine up to 900 c.c. at the first injection; there was a minus 1 pressure, with absolutely no discomfort in the patient, when suddenly, just as he was withdrawing the needle the patient turned pale, the pupils dilated, the patient broke into a profuse perspiration and his heart action became weak, but he did not lose consciousness. The interesting thing about it is that this happened just at the end of about 15 minutes' injection of 900 c.c. of gas, and the pulse, instead of getting rapid and irregular, became slower and slower until it reached a minimum of 48, showing probably a reflex vagus action. There is a possibility of producing a small lesion either in another portion of the lung or in the opposite lung a focal tuberculin reaction, as Brauer and Spengler have reported.

DR. BALDWIN: Knowing that the depth of Drs. Floyd and Robinson's needle was sometimes a little hard to gauge, I had a special needle made to gauge the depth of insertion. One may not need it, but in re-fillings I have been obliged to work without any assistant, and I think that in using one hand on the needle and resting this on the chest, prevents the needle from going too deep, and in the primary operation it may serve a purpose in maintaining the needle at the right depth, not allowing it to come out before the nitrogen has begun to flow in. It is also an advantage not to allow the needle to pull back.

DR. POTTENGER: This operation is one particularly for the hopeless cases of tuberculosis. There is the difficulty,—in knowing when a patient is hopeless. When the heart is able to do its work well and he is able to assimilate his food, there are some chances of recovery. I have been observing it in Brauer's Clinic in Europe, but have not done any of it. What is its actual value in arresting the disease, and also about what is the percentage of cases in which difficulty in performing it is found? I am intensely interested.

DR. C. L. MINER: I have performed this operation on some 20 odd patients. I feel that it is chiefly of value to us in cases otherwise hopeless, in which the chance of recovery is small. In this type of case, in which the mortality would be nearly 100%, I have saved 3 cases out of 21. They were otherwise certainly doomed. One danger is the danger of waking up the other lung. You cannot expect it to be perfectly healthy. My own rule would be that if there were anything wrong with more than one-third of the other lung you could not go ahead. I had a case of advanced cavity in one lung, with high fever. I gave her injections. The effects were phenomenal; the temperature dropped to normal, the pulse to normal. Her appetite increased and she felt like a new woman. Fortunately, at the end of three weeks, after the most remarkable improvement, the other lung waked up and I had to take out the gas, and in two months she was dead. I think it is extremely important to use the radiograph in these cases. It will enormously handicap your efforts to be without it.

Now, as regards cases to which I have done harm. I have hastened the death of one patient, though not in a case that could have recovered. It seems to me that it is a wonderful thing if it saves one case out of 100.

DR. J. E. ELLIOTT, Toronto: Dr. Floyd has become enthusiastic over some of the good results that he has seen. He said that some early cases recovered because of the injection. I wonder whether they would not have recovered without it. I would like to ask the question, where the fluid forms after a pneumothorax has been performed in a dry case does it show the characteristics of an exudate or of a transudate; is it inflammatory in its character or purely hydropic? May I ask where pneumothorax has resulted in the rupture of the lung, breaking through into a pus cavity, what pressure has been used in these cases? Has it occurred only in those cases where a high pressure has been used?

DR. FLOYD: In regard to Dr. Otis' statement that the Germans believe that pleural shock is due to embolus, I would say that no gas had been injected into this man, only the needle was introduced; therefore there was no chance of an embolus. Nitrogen was used in preference to air because it is less readily absorbed; probably it stays in the chest two-thirds longer than ordinary air. I agree with Dr. Miner in regard to the value of the x-ray in indicating when it is time to continue with the injections; but I also believe that when you find negative pressure you have waited too long instead of not long enough. I believe 50 or 60% of unilateral cases may be arrested by nitrogen. Dr. Elliott asks why I state that early cases were arrested by this process. The early cases that I have treated, arrest was brought about in a very few weeks, once or twice in two weeks. That is a much more rapid loss of moisture than can be obtained by other methods. As to effusions being inflammatory or transudates, I would say they are probably transudates.

DR. LAWRASON BROWN of Saranac Lake, New York, read a paper entitled,

WHEN IS A TUBERCULOUS PATIENT CURED?

Dr. Brown reviewed early definitions of cured phthisis and stated his conception of the word "cure" as meaning a restoration of the body to a state in which no vestige whatsoever of that disease exists within the body, although in certain instances some scarring is left behind. That a well-defined cavity can ever fully heal without leaving at least a fistulous cicatrix, is highly improbable, but it is entirely possible that in such patients with long "ultra-chronic" disease, the tubercle bacilli may finally disappear. We hear of "apparent" cures, "relative," "economic," "practical," "working" cures, and so on. Those who use these terms confess their doubts. On the other hand are those who "for the good of the cause" (the eradication of tuberculosis) still believe that the general public needs pap and not strong meat, honied words and not real truth. They advance expediency to uphold their position and fear the loss of funds for sanatoriums. Dr. Brown referred to Dr. V. Y. Bowditch, who through long experience saw the light when many of us were still in darkness and for years never used the term "cure" and now uses it only under protest. Dr. Brown believes that pulmonary tuberculosis is curable; that spontaneous healing of tuberculous infection occurs frequently; that healing of clinical tuberculosis may, but rarely does, occur; that permanent arrest is the most frequent termination of the disease in those who are later able to follow their usual occupations; that temporary arrest, of longer or shorter duration, occurs in all except the acute cases and that continuously progressive disease follows only upon several temporary arrests.

DR. C. C. BROWNING read a paper on,

A YEAR'S OBSERVATION OF SYMPTOMS IN CASES OF ADVANCED TUBERCULOSIS IN THE LOS ANGELES COUNTY HOSPITAL IN CONNECTION WITH WEATHER CONDITIONS.

The author had previously reported to the society the apparent influence on temperature and hemorrhage in tuberculous patients with reference to certain meteorological phenomena. Unseasonable or very sudden changes in temperature appeared to influence temperature in patients, while equal or greater changes occurring slowly did not. In the present report the patients were all in the advanced stages; 61 cases were charted and these embraced 21,968 patient-day observations. The charts covered the months August to March inclusive. Another chart showed the relation of temperature, humidity and rainfall to the number of deaths from tuberculosis in 1910. On a rising barometer with falling humidity with wind west of north and a clearing day the patients were pleased or jovial and optimistic; with reverse conditions they were pessimistic, cross, very irritable and some of them unreasonable in their demands. With the so-called "Northers" there is discomfort and increased nervous tension. This was noticed also in the lower animals.

DR. JOHN M. SWAN, of Rochester, N. Y., read a paper giving the details of the differential leucocyte counts in eight cases in which tuberculin injections were made for diagnostic purposes, in order to determine, if possible, the influence of tuberculin on the eosinophile leucocytes.

Case 1. Eosinophile before the injection of tuberculin, 2.3%, 3.2%; after the injection of 5 milligrams of tuberculin, 7.8%. Tuberculin test positive.

Case 2. Eosinophiles before the injection of tuberculin, 0.4%, 0.2%; after the injection of 3 milligrams of tuberculin the eosinophiles disappeared from the peripheral blood and remained absent until the patient died. Reaction negative.

Case 3. Eosinophiles before the injection of tuberculin, 5.6%, 5.0% (Ascaris lumbricoides infection); after the injection of 5 milligrams of tuberculin, 10.8%. Reaction positive.

Case 4. Eosinophiles before the injection of tuberculin, 5.2%; after 3 milligrams of tuberculin were injected, 9.%; after 5 milligrams of tuberculin were injected the eosinophiles disappeared. Reaction positive.

Case 5. Eosinophiles before the injection of tuberculin, 4.2%; after the injection of 1 milligram of tuberculin, 8.4%. Reaction positive.

Case 6. Eosinophiles before the injection of tuberculin, 3.8%, 1.6%; after the injection of tuberculin no increase in the eosinophiles. Reaction negative.

Case 7. Eosinophiles before the injection of tuberculin, 6.4% and 1.2%; after the injection of 5 milligrams of tuberculin, 4.0%. Reaction negative.

Case 8. Eosinophiles before the injection of tuberculin, 4.0%; after the injection of 3 milligrams of tuberculin, 8.8%. Reaction positive.

In these eight cases eosinophilia was seen after the injection of tuberculin for diagnostic purposes, in five cases and was absent in three cases. In the five cases in which the eosinophilia was observed there was a positive reaction. In the three cases in which eosinophilia was not found, the reaction was negative. One might draw two conclusions from these results: First, that eosinophilia is due to the fever accompanying a positive reaction. Second, after the injection of five milligrams of tuberculin in a person who is not suffering from bacillus tuberculosis infection, not enough tuberculin is administered to produce the eosinophilia.

The first conclusion must be rejected because all elevations of temperature are not accompanied by eosinophilia. The second conclusion may or may

not be justified. I have no evidence to offer upon that point.

DR. WILL HOWARD SWAN, of Colorado Springs, reported,

SIX CASES OF TUMOR OF THE LUNGS AND MEDIASTINUM SIMULATING PULMONARY TUBERCULOSIS.

These patients had been sent to Colorado at much sacrfice. One was a lymphosarcoma of the mediastinum in a woman aged 30. At autopsy it was found to be of the size of a child's head. No macroscopic evidence of tuberculosis anywhere. The second case was a primary carcinoma of the lung, in a man aged 53. He had slight expectoration for four months; lost 28 pounds and had moderate fever; sputum blood-stained a few times, but had shown no bacilli on several examinations; positive skin tuberculin test. At autopsy the left lung was a tumor mass.

The third case was of persistent thymus, possibly Hodgkins' disease, in a woman of 40. The others were of malignant disease. The diagnosis and clinical symptoms in all these cases were detailed. The differential diagnosis was gone into fully, but this was acknowledged to be impossible early in the course of these cases.

Book Reviews.

The Modern Treatment of Nervous and Mental Diseases. By American and British authors. Edited by WILLIAM A. WHITE, M.D., and SMITH ELY JELLIFFE, A.M., M.D., Ph.D. Vol. II. 8vo. pp. viii, 816. With 50 plates and 85 illustrations in the text. Philadelphia: Lea and Febiger. 1913.

The second volume of this new work on treatment has appeared very soon after the first, and confirms the favorable verdict pronounced upon its predecessor. This volume deals almost entirely with the diseases of the nervous system, diseases of the mind and some nervous diseases having been discussed in the previous volume. The first chapter, on the treatment of the neuralgias and neuritides, by Dr. S. I. Schwab, is wholly inadequate, omits various types of disease from any consideration, and neglects many important factors in treatment. Mr. James Sherren's chapter on the injuries of nerves, on the other hand, is, as might be expected, an admirable essay on the subject from the surgical standpoint. Dr. I. Abrahamson writes on muscular atrophies and dystrophies,—a chapter which contains considerable irrelevant matter, much overelaboration, and is rather unsatisfactory in its general aspect.

Dr. Jelliffe's chapter on the treatment of headaches is comprehensive and adequate. Dr. H. H. Hoppe sums up our knowledge of the treatment of spasmodic disorders satisfactorily. Dr. J. F. Munson's article on the treatment of the epilepsies is written from the asylum standpoint and is ill adapted for the general practitioner. He emphasizes the tendency to dementia, the inability to engage in productive labor, and the necessity of institutional treatment, and holds the New York prejudice against the use of bromides. The physician called upon to treat the epileptic with comparatively infrequent attacks, who shows slight tendency to mental deterioration, and who is out in the world earning his living and filling his place adequately in the community, will find little help in this pessimistic chapter. Dr. W. J. M. A. Maloney deals with the meningitides in an inadequate fashion, inserting a section on the meningeal form of poliomyelitis, and paying scant attention to otitic meningitis. The other cerebral complications of otitis, by the way, receive little attention. Dr. Jelliffe's long article on syphilis, supplemented by Dr. H. J. Nichols' chapter on salvarsan, is a very complete and exhaustive treatise on our present knowledge of all forms of syphilis of the nervous system, including the so-called "para-syphilitic" affections. It is very full and up to date and is the best chapter in the volume. Dr. Frederick Tilney contributes an over-elaborate but not especially complete chapter on the treatment of vascular lesions of the brain. Dr. S. A. Kinnier Wilson gives a clear and instructive account of the treatment of aphasia and apraxia. Dr. E. W. Scripture's article on stuttering is an excellent presentation of his own methods of instruction, which have proved so helpful in many cases. Dr. C. K. Russel discusses the treatment of the diseases of the cranial nerves and spinal cord in a somewhat incomplete manner. Dr. Gordon Holmes gives a clear account of diseases of the thalamus, mid-brain and cerebellum, with comparatively little to say, as might be expected, in regard to treatment. Dr. C. D. Camp's chapter on paralysis agitans and multiple sclerosis is of much value and presents the results of his own careful investigation of these diseases. Dr. Louis Casamajor sums up the treatment of the toxemias of dangerous trades and drugs. Drs. A. E. Halstead and R. T. Vaughan give an admirable summing up of the methods of surgical treatment of the brain and cord.

The editorial work in the present volume seems less thorough than it was in the previous volume. The selection of subjects is certainly open to criticism. We can see no satisfactory reason for assigning chapters on a purely anatomical basis, such as those assigned to Drs. Russel and Holmes, as if the location of a lesion had a special influence upon its treatment, except in regard to possible surgical interference. Furthermore, certain serious omissions are to be noted. Encephalitis, brain abscess and sinus thrombosis receive only cursory mention and tumors of the brain are considered very inadequately and in several different chapters. Nevertheless, in spite of these grave defects, and the other defects common to all composite works, there is much of value in this volume, which confirms the favorable opinion which we gave in the review of the first volume.

THE BOSTON
Medical and Surgical Journal

THURSDAY, MARCH 12, 1914.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States. $6.56 per year for all foreign countries belonging to the Postal Union.*

Papers for publication, and all other communications for the Editorial Department, should be sent to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston. All orders for reprints must be sent in writing to the Editor on or before the day of publication.

The Journal will furnish 100 reprints free, if requested in writing.

All letters containing business communications, or referring to the publication, subscription or advertising department of the Journal, should be addressed to the undersigned

Remittances should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

A NEW LEPER HOSPITAL AT PENIKESE.

THE outcome of House Bill No. 136, providing for a hospital building at the leper colony on Penikese Island should be favorable, judging from all previous legislation regarding questions for the care and treatment of others of our Massachusetts population who are not more unfortunate. No one can question the imperative need of a modern building for the care and special treatment of the lepers. For a number of years Massachusetts has looked upon these unfortunates in any but a proper light. Deprived of their liberty, segregated on a most desolate island, and because of difficulties of administration, practically unprovided for from a medical point of view, these people have, until recently been allowed to exist and nothing more. It is undoubtedly the duty of the state to provide for them a hospital, baths and means for special medical treatment, as well as fire-proof living quarters. There should be no false economic reasons when it is a question of the duty of the state and of justice to persons in its care.

It was a matter for congratulation when the State Board of Charity, two years ago, began to insist forcefully that the unsatisfactory conditions at the Penikese institution must be supplanted by scientific medical treatment. Since then matters have improved, but are by no means to the credit of Massachusetts. Visitors to the island have had no difference of opinion as to the needs of the institution. The efforts of the State Board of Charity for a modern building with modern equipment is a step in the right direction.

Apart from the question of the care of the patients, it is well to pause and ask whether the state does not owe some protection to those individuals who are caring for the lepers. At the present time it is unlikely that the state can procure help with conditions such as they are; but there can be no reason why, with changes such as are planned, the state should not be able to attract and hold responsible and desirable persons to care for these unfortunate people.

We have had an opportunity of inspecting the hospital plans and approve of them most heartily. Every provision that a modern scientific institution should have has apparently been thought of, and when the legislature has provided funds for the erection of this building, we can afford to forget her past indifference and look with pride to the position which Massachusetts will take in the treatment and care of leprosy.

THE FEDERAL INCOME TAX AS IT AFFECTS THE PHYSICIAN.

To some of those whose income is derived mainly from fees for personal service of a professional kind, that provision of the income tax which requires that *debts* should be included as income seems unfair.

On the back of the blank form for income tax returns, there are two explanatory paragraphs which read as follows:

"13. Persons deriving fees or emoluments for professional or other services, as in the case of physicians or lawyers, should include *all actual receipts* for services rendered in the year for which return is made, *together with all unpaid accounts*, charges for services, or contingent income due for that year, if good and collectible."

"14. Debts which were contracted during the year for which return is made, but found in said year to be worthless, may be deducted from gross income for said year, but such *debts cannot be regarded as worthless until after legal proceedings to recover* the same have proved fruitless, *or it clearly appears that the debtor is insolvent.* If debts contracted prior to the year for which return is made were included as income in return for year in which said debts were contracted, and such debts shall subsequently prove to be worthless, they may be deducted under the head of losses in the return for the year in which debts were charged off as worthless."

It is inevitable, therefore, that many physicians have been confronted with the alternative

of paying the tax on a long list of debts or of placing the corresponding bills in the hands of a lawyer for collection.

The close personal relation between patient and physician, and the attitude of the conscientious practitioner who takes pride rather in the excellence of his work than in the return for the same combine to make it peculiarly embarrassing for him to resort to legal proceedings for the collection of bills. Rather than do this, we believe that some of our best physicians will pay the tax and fail to collect the money due them.

It seems pertinent to ask why the physician should be placed in this embarrassing position. Why was not the law so framed that the tax should be levied only on actual receipts of the year, exempting for this year income due before the law went into effect? This year's bills if not paid until next year could then have been included in next year's income and so on in succeeding years, and the individual would then be free from taxation on prospective income on the one hand, and on the other, he could, if he chose, dispense with legal means of collection without injustice to himself.

MEDICAL LEGISLATION. REGISTRATION OF NURSES.

THE members of the State Board of Nurse Examiners have found during the past three years that the benefit to be derived from the law which requires a nurse to take an examination before he or she can practice as a registered nurse, is more or less nullified by the fact that some nurses have in one way or another picked up enough knowledge to pass the required examinations, who, nevertheless, have not received thorough training. The board is unanimous in feeling that it should have the authority to send some suitable person to visit the schools that are undertaking to qualify nurses for state registration, in order to ascertain just what opportunity is given the pupils for practical and theoretical experience.

The Massachusetts State Nurses' Association is presenting a bill which embodies the recommendation that the board is making to the Public Health Committee. Dr. W. P. Bowers, secretary of the board, and president of the Massachusetts Medical Society, is going to present the nurses' bill at the same time the report is presented. Letters have been sent to superintendents of some of the largest hospitals and to several nurse superintendents of smaller hospitals in different parts of the state asking for endorsment or criticism of the bill which is to be presented. The replies have all been in favor of such an inspector. All honest schools are willing to be visited, and many are not only willing but are anxious to have some one to refer to who represents the State Board of Examiners. Such a person could be of great assistance in showing where schools are weak and in helping to remedy deficiencies if they exist.

It is believed that the Russell Sage Foundation will, in the not distant future, make an investigation of training schools similar to what has been done in connection with medical schools, and Massachusetts would be wise to authorize its state board, which consists of doctors and nurses, to prepare the way for this more disinterested investigation.

It is hoped that the medical profession will give its hearty support to this bill, House No. 1186.

AN UNFORTUNATE DECISION.

THE United States Supreme Court has recently ruled that in prosecutions under the pure food and drugs act, the government must hereafter "prove the presence of added poisonous or deleterious substance *in quantities sufficient to injure health.*" This is an unfortunate decision and will have the effect of greatly increasing the difficulty of enforcing this law, since it will remove from the reach of punishment such adulterations as, though perhaps harmless to health, are nevertheless frauds perpetrated upon an unsuspecting, unprotected, and defenceless public.

DEATH OF DR. ROTCH.

THE medical profession of Boston have suffered a great loss in the death, on Monday evening, March 9, of Dr. Thomas Morgan Rotch, professor of pediatrics in the Harvard Medical School. Dr. Rotch was not only of international eminence in his specialty, but was beloved in many families whose children he had cared for, and by many who gratefully remember, in their childhood, his always kind and pleasant personality as their physician.

MEDICAL NOTES.

A CASE OF SMALLPOX AT PITTSBURGH.—A case of smallpox was discovered on Feb. 28 among a

trainload of 300 immigrants at Pittsburgh, Pa. The patient was taken to the municipal hospital and all the passengers and train-crew were vaccinated.

HOSPITAL BEQUEST.—The will of the late Wilson D. Kistler, of Lock Haven, Pa., it was announced on Feb. 25, contains a bequest of $30,000 to the local hospital.

BOSTON AND NEW ENGLAND.

POLIOMYELITIS IN MASSACHUSETTS.—During the month of January, 1914, 14 cases of poliomyelitis were reported in Massachusetts, 4 of them being in Boston.

TONSILLITIS IN WAKEFIELD.—During the past fortnight there has been prevalent in Wakefield, Mass., a local epidemic of streptococcus tonsillitis, similar to those which of recent years seem to have become increasingly prevalent in Eastern municipalities and smaller communities. In Wakefield there have been about 400 cases, without fatalities. The milk and the water supply have both been decided to be not the source of the infection, which in this case, as is probably usually the fact, is considered to have been air-borne.

SCARLET FEVER IN BRIDGEWATER.—During the past three weeks scarlet fever has been epidemic at Bridgewater, Mass., where 25 cases of the disease have been reported. Local schools and places of public assembly have been ordered closed until March 17.

INSTRUCTIVE DISTRICT NURSING ASSOCIATION.—At the annual meeting of the Boston Instructive District Nursing Association, held last week in this city, Miss Mary Beard, as director, presented her annual report in part as follows, describing the work of the Association for the previous year.

"For the year ending Jan. 31, the receipts for the general work of the Association were $72,180.47, and $61,718.58 was expended. Legacies amounting to $900 have been received for the permanent fund, together with donations amounting to $3,131.82. A legacy of $2500 was made to the reserve fund.

"Three new nurses were added to the staff Feb. 6, 1913. We have now 49 salaried nurses, 2 domestic educators (visiting housekeepers), 5 hospital pupils, and 20 students. Last year at this time there were 43 salaried nurses, 5 hospital pupils and 19 students.

"The greatest change in the staff has come through the gradual accomplishment of a plan adopted two years ago—that of acquiring a permanent staff rather than temporary nurses who changed from time to time. In this way 22 permanent staff nurses have been added since February, 1912, and 16 of the 22 since last February. This is the most important change which has occurred this year. All these nurses are graduates of one or the other of our courses in public health nursing, that is, they are women who want to do this sort of nursing more than any other work, are full of enthusiasm and have made sacrifices to obtain a special education for it. The supervisors have been longer in their positions and the machinery of the stations is running more smoothly—all of which means less fatigue and more efficiency.

"During the year we have had 10,536 new patients and made 120,597 visits, 600 more patients than a year ago and 10,000 more visits. One-half of these are free patients. Many of these 5000 free patients are 'free' patients only because illness in the family was the one last expense impossible to meet. Among them there have been a good many real 'problem cases,' known to many agencies and helped by them. Twenty per cent. were life insurance company patients, 2 1-3% paid 50 cents, 5 1-10% paid 25 cents, 17 1-10% paid less than 25 cents, 47 1-3% paid nothing. We nursed 3183 Boston Dispensary patients, or 30 1-5% of the whole."

PUBLIC NURSES UNDER CIVIL SERVICE.—By a new ruling, made as a result of a movement initiated last fall by the Boston Milk and Baby Hygiene Association, all nurses employed by boards of health and school boards in Massachusetts have been placed under civil service rules, except in Boston, where they are governed by a special act of the legislature.

MEDICAL BEQUESTS.—The will of the late Rebecca Warren Brown, of Boston, which was filed recently for probate, contains a bequest of $10,000 to Harvard University, to be applied to the fund, created by Dr. Buckminster Brown, brother of the testatrix, for a professorship in orthopedic surgery. The residue of the estate is left in equal shares to the Perkins Institution for the Blind and the Industrial School for Crippled and Deformed Children.

NEW YORK.

EUGENIC MARRIAGE BILL.—Report from Albany states that on Feb. 26 a eugenic marriage bill was introduced before the State Assembly. The bill requires that to obtain a marriage license the applicant must present a physician's certificate that the former is "free from phys-

ical or mental disease likely to be contagious or hereditary."

REPORT OF NEW YORK MILK COMMITTEE.—The seventh annual report of the New York Milk Committee, published on Feb. 26, shows that during the seven years from 1907 to 1913, inclusive, 950,000 babies were born in New York City.

"If the infant death-rate of the five years previous had prevailed there would have been 150,000 infant deaths instead of the 109,000 which actually occurred. On the other hand, if New York's low death-rate of 1913, *i.e.*, 101.9 per 1000 births, had prevailed throughout the seven-year period, only 96,000 babies would have died out of the 950,000 born. The committee points out that this record is not due to favorable weather conditions nor to other general accidental causes. Returns from the larger cities throughout the country, for 1913, published in tabular form in this report, show that while New York made a further reduction in 1913 in the actual number of deaths over its low record of 1912, Chicago, Philadelphia, Cleveland, St. Louis, Pittsburgh, Detroit, Buffalo, New Orleans and Toledo all show an increase."

MENINGITIS ABOARD A GREEK STEAMER.—Four cases of cerebrospinal meningitis have recently developed on board the Greek steamer *Athenae*, which was detained on its arrival at this port on Feb. 28.

REPORT OF THE ST. LAWRENCE STATE HOSPITAL.—The recently published twenty-seventh annual report of the board of managers of the St. Lawrence State Hospital, at Ogdensburg, N. Y., to the State Hospital Commission, records the work of that institution for the year ended Sept. 30, 1913. During this period the total number of patients under treatment was 2294, of whom 1074 were men and 1220 women. There were 152 patients who died, upon 98 of whom autopsies were performed. The course in the training school has been lengthened to three years, on account of which no class was graduated this year.

NEW YORK DEATH-RATE.—There were 1812 deaths, or a death-rate of 16.93 per thousand of the population, reported during the week ending Feb. 28, 1914, against 1699 deaths, and a rate of 16.50, in the corresponding week of 1913, an absolute increase of 113 deaths and an increase of .43 of a point in the rate, equivalent to a relative increase of 46 deaths. The following causes showed a decreased mortality: Diarheal diseases, bronchitis, broncho-pneumonia, all other forms of tuberculosis, and Bright's disease of the kidneys. The mortality from measles, whooping cough and lobar pneumonia were approximately the same as that of the corresponding week of last year. The following causes showed material increases: Scarlet fever, diphtheria and croup, typhoid fever, cerebrospinal meningitis, influenza, diseases of the digestive system other than diarrheal diseases, diseases of the nervous system and organic heart diseases, the increased mortality of the last mentioned being more than that of the sum of all other causes.

The number of children dying under one year of age was exactly the same as that of last year; that of children under five years showed a slight decreasse; at all other age groups the mortality was greater, especially among the extremely aged.

The death-rate for the first nine weeks of 1914 was 15.00 per one thousand of the population as against the rate of 15.47 for the corresponding period of 1913, a decrease of .30 of a point.

6. TANENBAUM, S. A. *A Consideration of Objections to Psychanalysis.*
7. OLMSTEAD, M. P. *The Value of Absorption Methods in the Wassermann Test.*

1. Conner discusses the merits of the intravenous method of administering salicylate of sodium in rheumatic infection. He says that the analgesic effect of the drug is more pronounced when given in this way, provided that the technic is correct and the preparation pure. The method is safe, painless and easy. Its application will probably be limited, but it offers something in cases where salicylate is not well borne by the stomach, where the ordinary method does not produce results, in cases with beginning heart involvement, and in rheumatic conditions of the eye. 5. CONNELL, R. *The Use of Ionic Medication in the Treatment of Certain Venereal Diseases.*
6. JARDINE, R. *Rapid Delivery in Eclampsia.*

1. Mitchell in this paper discusses (*a*) technic, (*b*) relationship of clinical data and milk supply, (*c*) relation between channels of infection and groups of glands involved, and (*d*) channels of infection. Under technic he describes his methods of studying 72 consecutive cases of tuberculous cervical glands in children; this part of the paper is very technical, describing variations in growth of the different strains of bacilli, differences between human and bovine types, culture media, etc. In the next part of his paper he describes his results. Of these 72 cases, 65, 90%, were due to the bovine bacillus, and 7 cases, 10%, to the human organism. As to age incidence, he comes to the natural conclusion that the use of unsterilized cows' milk is responsible for the large number of cases due to bovine origin in the very young children, 84% of whom were bottle fed. He could not find that one type of child was liable to this disease. There was seldom any interference with general health, many being in robust health. In only 3 instances could family exposure or a family history be obtained. He goes on to show the very large amount of tuberculosis among cattle in and around Edinburgh and urges more efficient legislation on the subject. He then considers the channels of infection and describes the groups of glands involved. In his experience there are two types of glands involved, one those showing little or no tendency to break down; and the other, those in which caseo-necrotic changes are the distinctive features. He believes the mouth and the naso-pharynx to be the avenues of infection. Out of 64 cases of tuberculous cervical adenitis, in 37.5% lesions of the tonsils were evident. His conclusions are sane and sound.

2. Robinson in a short paper discusses the anatomy, mode of production, diagnosis and treatment of torn semilunar cartilages, and describes 24 cases. [J. B. H.]

2. *PRINGLE, S. S. *Anatomy and Treatment.*
3. GRAY, H. M. W. *Etiology and Treatment.*
4. CHAPPLE, H. *Effects on the Female Generative Organs.*

1. In this paper Adami combats strongly the well-known views of Arbuthnot Lane on auto-intoxication, etc., concluding that it is more rational to regard the evil effects of intestinal stasis as a low form of infection than as a chronic intoxication. He believes the term gastro-intestinal auto-intoxication to be a much abused one, which should be dropped. Many of the symptoms attributed by Lane to intestinal stasis may arise from other causes, and therefore, before recommending the operation of short circuiting fullest investigation should be made. Usually other causes will be found which will render this unnecessary. (This is a timely article and a much needed one.—J. B. H.)

2. Pringle considers the various anatomical abnormalities which may cause stasis, such as ptosis, bands, folds, membranes, etc. These he describes in some detail. He takes up the symptoms, toxic and obstructive. Under treatment he considers prophylaxis, medical and surgical measures. [J. B. H]

6. *MILLER, J. *The Prevalence of Living Tubercle in Edinburgh Milk.*

1. This article describes in considerable detail the complex subject of the rationale of tuberculin therapy. The writer devotes considerable space to the preparation of that form of tuberculin with which his name is connected and describes experiments to substantiate his claims. He is of the opinion that tuberculin should be regarded as *a curative*, and not an immunizing agent. He describes the methods of administering his tuberculin as to dosage, etc. He urges early tuberculin treatment as soon as the diagnosis is established, ruling out, of course, all acute advanced cases.

2. This is a short general clinical article on the prevention and cure of certain forms of nervous exhaustion coming under the general term neurasthenia. There is much sound common sense advice in this paper.

3. In a long paper Watson takes up the pathological basis for intestinal toxemia as shown by constipation, catarrh of the large bowel, dilatation, adhesions, kinks, etc. He considers the factors regulating normal intestinal functions and evidence of normal functioning as shown in the stools and urine. He devotes much space to the diagnosis of intestinal stasis, as shown by x-rays, and takes up briefly the clinical conditions induced by intestinal toxemia, such as those under the neurasthenic group, the rheumatoid group and the dyspeptic group. He describes briefly the so-called Lane's kink, Jackson's membrane, and various other kinks and malformations.

6. Miller confirms the work of Fraser and Mitchell, and explains the large amount of bovine tuberculosis in Edinburgh by analyzing samples of milk in that district, in 13% of which (104 samples) he found live tubercle bacilli. [J. B. H.]

3. Jaffé reports the histological changes found in various cases of fatal benzin poisoning. These observations were confirmed by a series of experiments in which animals were killed with benzin introduced either intravenously or by mouth. The poisoning is either acute or chronic, depending on rapidity of absorption. In acute cases the drug is excreted through the lungs, producing characteristic minute hemorrhage; in cases of chronic poisoning it causes degenerative foci in the liver and kidneys. No chemical changes or evidences of hemolysis were found in the blood. The lesions in both man and animals were essentially similar.

The practical significance of this study is that since benzin is taken up from the intestines slowly, active purgation is always recommended as a therapeutic means.

4. Simmonds reports three examples of secondary tumors in the hypophysis which appeared to produce symptoms of diabetes insipidus. He has seen six other cases, however, with lesions through the entire hypophysis where there was no polyuria.

The literature on the subject points to the belief that hypophyseal destruction and diabetes insipidus are closely related. Despite his latter findings, Simmonds does not consider this disproven.

He concludes that hypophyseal metastases are relatively common in malignant disease and believes that polyuria may be an early symptom of this peculiar lesion. [R. F.]

Correspondence.

RECIPROCITY.

SAN FRANCISCO, Jan. 29, 1914.

Mr. Editor: I am enclosing a letter from Doctor Alderson who is a member of the California State Board of Medical Examiners, in reply to a letter I wrote to him asking why the medical license of Massachusetts was not accepted by the California State Board.

I thought perhaps it might be a weapon which you could use to effect a change in Massachusetts requirements, for you know that all the men coming out to California at least, cannot have reciprocity with Massachusetts. Fortunately I had an Ohio license which procured affiliation for me.

Hoping that this enclosure may be of some use, I am

Yours sincerely,

WILLIAM PALMER LUCAS, M.D.,
Professor of Pediatrics,
University of California.

[ENCLOSURE.]

SAN FRANCISCO, Jan. 6, 1914.

My dear Dr. Lucas: In reply to your inquiry regarding the status of Massachusetts State Medical licenses, I beg to state that the California State Board of Medical Examiners has refused to grant reciprocity licenses to applicants presenting Massachusetts State licenses. The reason for this unfortunate state of affairs is that Massachusetts does not

require an M.D. degree of applicants who come up for examinations for licenses.

Regretting very much that this is the case, I am

Cordially yours,

HARRY E. ALDERSON, M.D.

Miscellany.

CHANGES IN THE MEDICAL CORPS, U. S. NAVY, FOR THE WEEK ENDING FEB. 28, 1914.

February 20, Medical Director C. F. Stokes, detached from Bureau of Medicine and Surgery, Navy Department, and ordered to command Naval Hospital, Philadelphia, Pa.

Medical Inspector G. A. Lung, detached from command of naval hospital, Philadelphia, Pa., and ordered to Naval Training Station, Newport, R. I.

Surgeon J. F. Leys, detached from Naval Training station, Newport, R. I., and ordered to duty in connection with the fitting out of the *New York* and to duty on board when that vessel is placed in commission.

Medical Inspector L. W. Spratling, detached from Naval Recruiting Station, Atlanta, Ga., and ordered to duty as fleet Surgeon of Atlantic Fleet, *Wyoming*.

P. A. Surgeon C. E. Strite, ordered to the Naval Recruiting Station, Atlanta, Ga.

Surgeon H. D. Wilson, detached from the Naval Recruiting Station, Boston, Mass, and ordered to the *New Jersey*.

Assist. Surgeon E. P. Halton, ordered to Naval Recruiting Station, Boston, Mass.

February 24, Surgeon R. F. Sheehan, detached from marine advance base brigade of Atlantic Fleet to home and wait orders.

P. A. Surgeon J. P. Haynes, ordered to the Naval Training Station, Great Lakes, Ill.

P. A. Surgeon E. L. Woods, detached from the Naval Proving Grounds, Indian Head, Md., directed to wait orders.

Feb. 26, P. A. Surgeon H. L. Dollard, detached from the *North Dakota* and ordered to the Naval Hospital, New York for treatment.

P. A. Surgeon P.R. Stalnaker, ordered to the *North Dakota*.

MASSACHUSETTS GENERAL HOSPITAL.

SURGICAL MEETING.

A surgical meeting open to the medical profession will be held at 8.15 p. m. on March 13, 1914, in the lower amphitheatre of the Out-patient Department. Entrance on either Blossom or Fruit Streets.

Dr. G. W. W. Brewster will present "Report on Cases of Pelvic Inflammation."

Dr. Lincoln Davis will present "Report on Cases of Renal Surgery."

FRANKLIN COUNTY DISTRICT MEDICAL SOCIETY.

The bi-monthly meeting of the society was held in Greenfield, January 13th. A letter was read with reference to a bill now before the legislature regarding the revelation of professional secrets in court on the part of physicians and nurses. The suggestion offered was that the words "not be urged" should be changed to "not be compelled." Dr. G. P. Twitchell of Greenfield read a paper on the Treatment of Gastric Ulcer. The paper was discussed by Drs. H. G. Stetson and Charles F. Canedy of Greenfield and by Dr. Philbrick of Northfield. Dr. Paul W. Goldsbury of Warwick read a paper on Observations on the Sense of Smell and gave a demonstration.

SOCIETY NOTICES.

THE HARVEY LECTURE.—The tenth lecture will be delivered on Saturday, March 14, at 8.30 p. m., at the New York Academy of Medicine, 17 West 43d Street, by Prof. W. T. Halsted, of Johns Hopkins University.

Subject: "The Significance of the Thymus Gland in Graves' Disease."

THE BOSTON SOCIETY OF MEDICAL SCIENCES.—The next meeting will be held on Tuesday evening, March 17, 1914, in the amphitheatre of the Administration Building of the Harvard Medical School, at 8.15 o'clock.

Program:

Dr. Otto Folin and Dr. W. Dennis: "An Interpretation of Creatine and Creatinine in Relation to Animal Metabolism." (20 minutes.).

Dr. L. W. Hackett: "A New Air Filter." (20 minutes.)

Dr. H. T. Karsner, Mr. H. H. Amiral and Mr. A. V. Bock: "A Study of the Influence of Splenectomy on Hemopsonins in the Blood and in Various Organ Extracts." (15 minutes.)

THOMAS ORDWAY, *Secretary and Treasurer*,
Harvard Medical School.

BOSTON MEDICAL LIBRARY in conjunction with the SUFFOLK DISTRICT MEDICAL SOCIETY.—Surgical section meeting, John Ware Hall, Wednesday, March 18, 1914, at 8.15 p. m.

"Brain Tumors," Dr. E. H. Nichols. Discussion by Drs. P. C. Knapp, J. J. Thomas and E. W. Taylor.

Light refreshments after the meeting.

FRED B. LUND, M.D., *Chairman*.
HORACE BINNEY, M.D., *Secretary*.

RECENT DEATHS.

DR. LAZARUS SCHONEY, who died on Feb. 18 in Coney Island, N. Y., was born at Budapest, Hungary, in 1838. He studied medicine at Prague, and, after coming to the United States in 1860, at the University of Pennsylvania. He served during the Civil War as a surgeon in the Union army, and subsequently was pathologist for a time at the Lincoln General Hospital, Washington. In 1868 he settled in the practise of his profession at New York City. He became professor of pathology in the New York Medical College, and was the author of several works on pathology and biology. He is survived by his widow.

DR. JOHN FREDERICK WELCH, who died on Feb. 23 in Quincy, Mass., was born at Boston in 1854. He received the degree of M.D. in 1880 from Bellevue Hospital Medical School, New York. He immediately settled in the practise of his profession at Quincy, where he was for several years city physician and member of the local board of health. He was a Fellow of The Massachusetts Medical Society, a member of the Norfolk South Medical Society, and president of the Quincy Medical Club. He was consulting physician and secretary of the Quincy Hospital. He is survived by his widow, one daughter, and a son.

DR. IRA HOPKINS of Utica, N. Y., died on Feb. 23, at the age of 80 years. He was graduated from the medical department of the University of Buffalo in 1859.

DR. ANNA MARLIN CORNWALL, who died on March 1, at Brookline, Mass., received the degree of M.D. in 1906 from the Tufts Medical School. She was a Fellow of The Massachusetts Medical Society.

DR. FRANK SARGENT GRANT, of New York, a graduate of the College of Physicians and Surgeons in 1875, died on March 3.

DR. JOHN PRINGLE, of East Newark, N. J., died from pneumonia on February 25, at the age of 68. He was a native of Glasgow, Scotland, and was graduated from the University of Glasgow in 1875. Dr. Pringle had been president of the East Newark Board of Health since its organization a few years ago.

NOTES ON THE NEW COOLIDGE X-RAY TUBE.

By H. W. Van Allen, M.D., Springfield, Mass.

The ability of any mechanical device to be useful is limited to the ability of the weakest part to withstand the strain put upon it. When we are dependent upon such a mechanical device for medical deduction it is self-evident that the medical information is limited in the same way. It has been a well known fact to Roentgenologists for some time that the weakest part in our equipment has been the tube. The exciting apparatus has been gradually increased in efficiency until in the interruptless machine, as now made, we have electrical output enough to destroy the ordinary tube in a few seconds. The tube makers have tried to take care of this electrical bombardment by backing up the platinum target by large quantities of copper to absorb the heat generated. Again a step forward was the substitution of tungsten in the target for platinum. This was a valuable addition as the melting point of tungsten is some 2,000 degrees, Fahrenheit, higher than platinum; therefore it withstands the impact of the cathode ray much better. Here seemed to come the limit, however. The various makers claimed certain points of superiority but the advantages were minor and all tubes had the same limitation.

It has been left for Dr. W. D. Coolidge to solve the problem in a most efficient way. For two years past experimental work has been carried on which has resulted in a new type of tube dependent upon entirely new principles. While Dr. Coolidge does not believe the tube is beyond improvement he feels clinical experience is now needed to obtain from the actual workers practical suggestions. To this end a half dozen of these tubes have been placed in the x-ray laboratories of physicians.

Besides Dr. Coolidge's original article in the *Physical Review* many of the scientific journals have published extensive papers on this new tube from which the daily press has printed more or less distorted reports. My object in presenting this short paper is that the readers of the Journal may know from a medical standpoint what those of us who are actually using the tube are expecting.

In all tubes the x-ray is produced by the cathode stream striking the anode, or target, from which is given off the wave energy called the x-ray. This cathode stream must be excited by bombardment of the cathode. In the old tube these were positive ions carried across by the small quantity of contained air in the tube. It was the variations in the quantity, character and position of this remaining air that made the character of the tube so unstable. The heavy target absorbed the air only to give it off in action, when heated by the bombardment of the cathode stream. Thus a tube would never be found of the same character at different times. When one realizes that only one condition of the tube fits a given requirement and the tube is constantly changing the problem has been not to get the best radiograph but to get as good as such varying conditions will allow.

With the Coolidge tube all this is changed. In general shape it is the same as the old style. The vacuum is as perfect as can be made, a thousand times greater than the old type. This being the condition not even the highest tension current will pass from cathode to anode. To overcome this a filament of tungsten has been placed in the cathode, connected by two low tension insulated wires through the cathode stem to a storage battery. The whole is so placed as to be insulated for high tension currents from the ground. The high tension current is connected to either of the low tension wires so it may be passed along to the cathode, while the anode is connected to the other high tension terminal. Until the battery current is completed and the filament lighted, no high tension current will pass. When the filament is lighted, however, current passes freely, the electrons coming from the heated filament. The penetration of the tube is dependent upon the rapidity of the electric discharge from the filament. This discharge is controlled by the heat in the wire which can be varied by a rheostat introduced into the battery circuit, so at will we can change to any penetration by merely moving a rheostat handle. Moreover, we have no particles of air to come out of the heated target and change the conditions of the tube. We have no secondary rays to heat the glass and decrease the clearness of the shadow. A tube of this kind can run continuously with a current that would ruin the ordinary tube in half a minute. Consider then the tremendous output of such a tube for treatment work. Filters placed in the path of the Roentgen ray will take the emanations not desired in a given case and still there is abundant capacity remaining. This together with the cross-fire technique makes therapy of internal diseases equally efficacious to that of the body surface. With such an instrument in our hands we have an opportunity for exactness never before thought possible by the Roentgenologist. Radiographs for stereoscopic work may have exactly the same character. Particularly brilliant plates may be exactly duplicated in future cases, because the various elements involved in the operation have become susceptible of exact measurements and control. The one thing we have needed so badly has arrived, and in a form that seems to me particularly free from objectionable characteristics.

SOME TRAGIC ASPECTS OF WHOOPING-COUGH.*

BY PHILIP H. SYLVESTER, M. D., NEWTON, MASS.

THE death of a child from any cause is a tragedy—but we are liable to lose sight of that fact in the sudden, unexpected, or dramatic death of an unusual case. Whooping-cough with a mortality of approximately 7 per cent., and a toll of ten thousand in the United States annually[1], presents an appalling contrast to the layman's, and the average physician's, conception of its harmlessness.

To you, as pediatricians, it is hardly necessary for me to speak in detail of the pathology of the disease; the causes of death in our usual experience are briefly, exhaustion, pneumonia, bronchopneumonia, cardiac, and terminal tuberculosis. The cases which I am about to describe are of interest owing to their unusual type and an argument for an efficient treatment of, as well as prophylaxis against, the disease. Inasmuch as six of the eight cases to be reported were much alike I will save your time by describing only one of these.

CASE 1. Marian R. Age 2 years.

F. H. Third child of well parents; two older children well except for last stage of whooping-cough.

P. H. Full term, transverse position, delivered by version. Received an intra-capsular fracture of the left humerus which healed with no deformity. Was breast fed for nine months, then various mixtures. Did perfectly well. Has always seemed a well, normal child.

P. I. Has been having whooping-cough for the last two weeks; has not been very sick. Last night about midnight had an unusually severe paroxysm, followed by a convulsion, seemed very feverish immediately after; has been delirious ever since and has had seven convulsions, has been stiff most of the time.

P. E. August 15, 1912, 10° after onset.

Well developed and nourished child, unconscious, rather cyanotic, breathing labored, much mucus in trachea; anterior fontanelle closed; pupils equal and do not react, are slightly dilated, occasional divergent strabismus; jaws are clenched; throat is clear except for large tonsils; there are a few large glands in the neck; the lungs are full of coarse rales and ronchi, no dullness or modified breath sounds; heart sounds regular, rapid, no murmurs, heart not enlarged; abdomen held rigidly; no täche; genitals negative. Extremities, except the left arm, in moderate spasm all the time, occasionally becoming more rigid in extension. Left arm flaccid, but is moved occasionally with waving motion, no elbow jerk. Knee jerks not exaggerated. Koernig not tried. No Babinski. Temperature 106; pulse 160; respirations 40. Lumbar puncture 45 c. c. clear fluid, considerable pressure, no clot in 12 hours. Cells 12 per c. m. m., largely lymphocytes and endothelial. Culture, no organisms in 48 hours.

Diagnosis. Cerebral hemorrhage.

* Read at a meeting of the New England Pediatric Society, Dec. 12, 1913.

FURTHER NOTES ON THE CASE.

August 17. Temperature persists. Has had eighteen convulsions since last visit. Signs unchanged except for retraction of head and stiffness of neck. Lumbar puncture, 60 c. c. faintly cloudy fiuid, clot in two hours. Noguchi +. Cell count 300, many endothelial, few mononuclear, many polynuclear; smear, no organisms seen. Culture sterile after 48 hours.

August 20. Acute symptoms persist. Had four convulsions yesterday, none today. Is still unconscious. Cries a great deal. Refuses all nourishment. Looks very badly. Stiffness and retraction of neck more marked. Pronounced täche cérébrale. Left arm flaccid, no elbow jerk. Other extremities spastic but in more or less constant motion. Knee jerks not obtained. No Koernig. Babinski present both sides. Lumbar puncture, 65c.c. *turbid* fiuid. Cell count not done. Clot in one hour, heavy. Tube clears on standing with about half an inch of sediment of polynuclears. Noguchi not done. Smear, no organisms seen. Culture, many staphylococci in 24 hours.

August 24. Seems a little stronger; still unconscious. Not so restless. Less rigidity. Temperature has gradually come down to 100, pulse 120. Swallows a little milk when put in mouth with spoon. Rigidity of other extremities and flaccidity of left arm persist. Babinski present on both sides. Lumbar puncture, 35 c. c. slightly turbid. Noguchi +. Clot in one hour. Cell count, 1,000 per c.m.m., all polynuclears. Culture, many staphylococci in 24 hours.

Child gradually got better but was still unconscious and presented moderate meningeal symptoms on September 15, 1912, when by lumbar puncture 15 c. c. clear fluid was obtained. Cell count 40, all mono-nuclears. Culture sterile.

Child remained unconscious for about five months from the onset, during which time it was fed by nasal tube; then gradually began to notice, to take food voluntarily and to have more or less coördinate actions.

It was seen again December 2, 1913, approximately a year and a half after the onset.

P. E. Poorly developed, fairly nourished. Seems fairly bright but is easily frightened. Mouth tends to remain open and the child drools constantly. Recognizes parents, brothers and neighbors and passing automobiles. Does not talk intelligibly, but indicates wants pretty clearly, and appears to understand when spoken to. It shows no paralysis although the left arm is soft, flabby, and a trifle smaller than the right; the elbow jerk is still absent and the child uses the arm very little but has all motions. Mother states that the child has eight to ten "contractions" in the arm daily; none noted during physical examination. Tries to walk when held up about as a child of ten or twelve months would do. Mentally is certainly not more advanced than the average child of two years.

CASE 2. Clarence E. Age 22 months.

F. H. Parents well. One brother has whooping-cough severely.

P. H. Full term, normal delivery, breast fed for three months, then various modifications of a proprietary food containing much starch and sugar. "Did fairly well." Has had frequent colds. Has

always been pale. Has been very slow in getting teeth. Does not walk. Talks very little.

P. I. Has been having whooping-cough (whooping) for two weeks; during the last week has had pretty severe paroxysms frequently; has vomited a good deal and has seemed a little feverish in the afternoons. Four days ago had a very severe paroxysm, followed by a convulsion lasting ten minutes, it is stated; has not seemed bright since.

Extremities have been stiff all the time but the left hand is frequently placed on the head. Has had a rectal temperature varying from 104 to 106 since shortly after the first convulsion. Yesterday and today the extremities have not been so stiff but have twitched a great deal. The child has looked badly and appears as if in pain, and has put the hand to left ear. Was seen by me to determine the question of otitis media.

P. E. Pale, under-sized child, fairly nourished, unconscious, a little cyanotic. Anterior fontanelle half an inch in diameter seems tense but not definitely bulging. Head is square. Ears negative. Eyes divergent, pupils widely dilated, do not react. Head retracted. Neck rigid. Throat clear. Six upper teeth, four lower, chalky.

Lungs full of coarse rales; much mucus in trachea; breathing is shallow and irregular.

Heart not enlarged; sounds very weak, very rapid, no murmurs made out.

Abdomen lax. Liver large, 2 cm. below costal border. Spleen not felt. No tenderness. Marked tâche cérébrale.

Knee jerks not obtained. Koernig on right, Babinski on both sides. Neck sign present. Extremities intermittently spastic with fingers and toes in position of tetany. Epiphyses of wrists and ankles much enlarged. Temperature 104°, pulse about 180, respirations 40.

Lumbar puncture, 40 cc. cloudy fluid under very much pressure. Clot in one-half hour. Cell count more than 1,000, all polynuclears. Smear shows occasional extra-cellular diplococcus resembling pneumococcus. Culture unfortunately thrown away. Child died five hours after lumbar puncture.

CASE 3. Richard D. Age 6½ years.

F. H. Only child. Parents well.

P. H. Full term, normal delivery, breast fed one year. Always well and strong up to six months ago when he had scarlet fever mildly, no kidney involvement. Has been well since, although "nervous" at times.

P. I. Has had pertussis for five weeks; has vomited a great deal but has felt pretty well and has been up most of the time. Paroxysms have been growing more severe for the last two weeks. Yesterday afternoon, after a severe paroxysm fell down and stayed "blue." Has been unconscious since; has been very feverish and delirious; no voluntary motions except that he swallows a great deal. Temperature was 103 by axilla this morning.

P. E. 1 P. M. 20 hours after the initial convulsion.

Well developed. Cyanotic, spastic in all extremities. Left pupil dilated, neither react. Cheyne-Stokes respirations. Lungs full of large, rattling rales.

Heart not enlarged. Sounds very rapid; no murmurs made out. Marked tâche cérébrale.

Abdominal wall rigid; no masses or apparent tenderness.

Knee jerks very much increased. Babinski present on both sides. Koernig not tried. Rectal temperature 105°, pulse 160, respirations 30.

Lumbar puncture, 45 cc. clear fluid, no clot in 12 hours. Noguchi not increased. Cell count 10, all lymphocytes. Smear, no organisms. Culture, no organisms after 48 hours.

Following lumbar puncture the child relaxed greatly; breathing became more regular and color improved. Spasticity and convulsive movements began again after about eight hours and continued until the child's death on the following day.

The other five cases of this type were from 18 months to six years old. Within the second to the fifth week of the paroxysmal stage all had a convulsion, or something like it immediately following a severe paroxysm. All had a very high temperature,—spasticity rather than paralysis. All had an increased amount of normal, sterile spinal fluid, and all died in from 10 to 48 hours of the initial convulsion.

It may be fairly assumed that all of these 8 cases were dependent, at the start, on a similar lesion, in that all presented, at the start, evidence of a diffuse process or processes in the brain and meninges. It seems to me that these symptoms are best interpreted as meaning high intra-cranial pressure, due to oedema or hemorrhage. As to oedema,—it is inconceivable to me that such a train of symptoms can come without warning, practically out of a clear sky. As to hemorrhage,—on the other hand,— the explosive character of the onset, during or immediately after a violent paroxysm, seems particularly consistent with hemorrhage,—a hemorrhage so large and producing so much pressure, that most of the focal symptoms were obscured.

In the first case it seems reasonable to assume that the case was one of hemorrhage at the start, the clot later becoming infected and producing meningitis, possibly encephalitis as well.

In the second case,—of course all that I found was a meningitis, presumably due to the pneumococcus, but the history and onset were so suggestive that I have no doubt that a cerebral hemorrhage was at the bottom of it.

It would be interesting to see what proportion of these cases become infected and have meningitis, if they live long enough.

CONCLUSION.

Here, then, are eight tragedies; seven cases dying immediately, one living but requiring unremitting care for a year and a half, and even now presenting no great promise of physical or mental development. Let us remember, however, that these are only eight—that all of the ten thousand deaths from this disease last year were just as surely tragedies; that a percentage of them was preventable by prophylaxis, and that another percentage—for surely there must have been a great many cases similar to those reported here—could have been prevented by appropriate treatment.

SUMMARY.

1. Certain cases of whooping-cough have symptoms of intra-cranial pressure, best explained on the ground of a cerebral hemorrhage.
2. The hemorrhage appears to be dependent upon the stress of a severe paroxysm.
3. The symptoms of hemorrhage in these cases pionted to lesions other than middle meningeal and were surprisingly uniform in the
(a.) Initial convulsion.
(b.) Immediate rise in temperature to a high degree.
(c.) Cyanosis.
(d.) Spasticity rather than paralysis.
4. This type of cases emphasizes the importance of prophylaxis.
5. Treatment should be directed toward at least reducing the severity of the paroxysms.

NEUROLOGICAL SOCIAL SERVICE, MASSACHUSETTS GENERAL HOSPITAL

BY MARGHERITA RYTHER, BOSTON,

Social Service Worker, Neurological Department.

INTRODUCTORY STATEMENT.

FOR seven years, under the auspices of the Social Service Department of the Massachusetts General Hospital, a worker has had charge of such cases in the Neurological Department as needed attention. The general result of this work under the immediate charge of Miss Edith Burleigh so far justified itself that it was thought desirable about a year ago (Dec., 1912) to make the relation between the Neurological Department and the Social Service Department still more intimate and presumably more efficient by having a social worker actually in the clinic, instead of at a distance, as the previous arrangement has been. Miss Margherita Ryther, Miss Burleigh's successor and former assistant, was appointed to this position and since then has had her desk in one of the rooms of the neurological out-patient department. She has thereby been brought into the closest possible relation with the actual practical work of the clinic. This has unquestionably resulted in an increase of efficiency in the treatment of patients, which it is always desirable to remember is the main object for which the clinic exists.

The significance of such an apparently trifling step as placing a social worker in immediate relation to the actual routine of a clinic is far-reaching. Wherever it has been attempted, so far as I am aware, it has met with success. It is certainly correct in principle unless the whole social service idea is wrong and that even the original doubters will not now be likely to admit. The demand for broad-minded, rational and honest treatment which Dr. R. C. Cabot has done much to foster has necessitated a broadening of the therapeutic outlook which finds expression in various ways but in none more definitely than in the closer alliance between bodily and mental conditions. A neurological clinic naturally offers peculiar opportunities for the development of such study as I believe a reading of the accompanying report will show. The growing conviction that many of the so-called functional disorders of the nervous system, at times regarded lightly by the physician, are of the utmost significance to their victims and to society at large, is being met by an adequate coöperation between medicine as represented by the doctor and external conditions as represented by the social worker. The time is rapidly approaching, if not already here, when such coöperation will be regarded as having passed the experimental stage and become established as a necessity of a well-ordered clinic. E. W. TAYLOR, M.D.

REPORT.

It is now nearing the end of the year since the Social Service Department was asked to transfer the social worker from the general department into the Nerve Clinic, and the results of the experiment are both encouraging and instructive. Through the closer relationship of doctor and social worker there is being developed a broader knowledge of their respective fields and a consciousness of the interdependence of the medical and social problems. This mutual understanding has resulted in a more vital coöperation.

There have been assisted by social service 315 patients (not counting the "clinical cases"—those not having a social record.) One hundred and twenty-seven of these are "new" and 188 are "old"; the number of new cases, being materially larger than in previous years. These totals of cases show only a part of the work done, since it has been necessary to decline several new cases after preliminary investigation and consequently these cases do not appear in either group, the patients recorded as "new" being only those of whom records were made. These new cases, of which 87 were referred by the clinic physicians and 40 by outside social agencies, were selected because of their urgency and need for investigation and "follow-up" work, and may be grouped under the following six headings:

1. Social investigation before making plans for disposition and treatment.
2. Social investigation before diagnosis is made.
3. Social study to supplement physician's treatment.
4. To get work.
5. Free treatment.
6. Miscellaneous.
7. Steering.

While the social treatment for each of these groups is dependent upon the results of the so-

cial investigation, the type and extent of the investigation must necessarily be determined by the need of the individual case. In general, however, the social investigation and treatment of these various groups may be considered in the following ways:

1. *Social investigation before making plans for disposition and treatment.*—Arrangements made for institutional, hospital, convalescent, vacation and suitable home care; work secured; free treatment.

The majority of patients coming under this group are suffering from organic nerve disease, and need social assistance in arranging for their admissions to the various state institutions, including schools for the feeble-minded, the insane hospitals, the epileptic colony, the state infirmary, the city almshouse, private homes for chronic invalids, small private hospitals, etc. A number need social supervision in their homes: *i.e.* instruction in hygiene, and "follow-up" work—oversight in seeing that they return to the clinic for treatment. Frequently the patients need financial help and the local relief agencies or relatives are called upon. There were 46 cases coming under this heading. These were divided as follows:

A. Diagnoses.		
(1) Neurosis		14
a. Epilepsy	7	
b. Chorea	4	
c. Occupational neurosis	2	
d. Gastric neurosis	1	
(2) Psychoneurosis*		4
(3) Organic cord disease		4
(4) Organic brain disease		2
(5) Psychosis and mental defect		14
a. Psychosis	6	
b. Mental defect	8	
(6) Unclassified (diseases other than nerve)		8
a. Arteriosclerosis	3	
b. Cephalalgia	1	
c. Debility	2	
d. Alcoholism	1	
e. Morphinism	1	
Total		46

B. According to Disposition.	
(1) Institutional and hospital care	22
(2) Sanatorium and convalescent	5
(3) Vacations	1
(4) Work	1
(5) Transfer to other social agencies	4
(6) Supervision in the home	12
(7) Purpose not accomplished	1
Total	46

2. *Social investigation before diagnosis is made.*—An extensive social investigation of the patient's inheritance, environmental conditions and personal history, requiring interviews with members of the family, school teachers, family physicians, employers and patient (if he is responsible enough to talk coherently).

Of this group the patients referred are usually those who show mental symptoms during the clinical examination and the physicians wish a report of facts from the family or someone who knows the patient well enough to report upon his history and behavior. The disposition in these cases is similar to that of those under No. 1, according to diagnosis made, except that in these cases the family and relatives are instructed more in detail as to the nature of the patient's illness and how they may assist in his treatment. If the patient is not proven to be suffering from insanity the socio-therapy method of treatment is frequently used (See under group 3.) There were eight cases under this heading.

A. Diagnosis.		
(1) Psychoneurosis		3
(2) Psychosis and mental defect		3
(3) Unclassified (diseases other than nerve)		2
a. Debility	1	
b. Alcoholism	1	
		8

B. Treatment	
(1) Insane hospital	1
(2) Sanatorium	1
(3) Supervision in home	1
(4) Transfer to care of other social agencies	3
(5) Transfer to care of family	2
	8

3. *Social study to supplement physicians' treatment.*—Socio-therapy—an analysis of the patient's environmental conditions, hereditary influences and temperamental tendencies as; (1) a basis for treatment; (2) as a curative influence. In the study and treatment of the psychoneuroses the social histories and conditions play an important part.

(1) The physicians in the clinic have not the time to study the causal social conditions contributing to the nervous invalidism of these patients, and the information secured is of value to them in rounding out their clinical examinations and making it possible to advise the best treatment. The many cases demanding their attention makes it necessary, in general, for them to confine their efforts to the physiological disturbances of the nervous system. The doctor in his private practice in treating one of these cases knows that frequently the nervous disorders may be traced to emotional conflicts which are often the outcome of faulty environmental conditions. He would not advise treatment without a knowledge of the patient's resources, social, financial or otherwise, but it takes time to secure these facts, and it is just here that the social worker in the clinic is useful, since by getting from the patient the needed data she saves the physician

* The term "psychoneurosis" is used in this report as a general term, to indicate neurotic states, predominantly mental in character, but not reaching the point of irresponsibility.

much time and the foundation is laid for good medical and social team-work, which is of decidedly greater value to the patient than either alone.

(2) The analysis is used secondarily as a medium for social and psychological treatment, the benefit to the patient being a clearer understanding of what nervousness means, the many causes contributing to nervous breakdown, and the means available for readjustment. He is made to see himself and his environmental conditions from an objective point of view. He learns to understand himself and his relation to others; he is enabled to review his life's development; he is made to face his faulty traits of character and unfortunate inherited tendencies. He sees not only his weak but also his good qualities and through this increasing knowledge and release from former self-ignorance the means and opportunity to reëstablish himself is provided. This breaking down of old habits, false beliefs, etc., cannot be accomplished at once. Self-knowledge is only the first step towards gaining emotional poise, but the light thrown upon the patient's life through the unravelling of his social background is the foundation of ultimate recovery. Through the social study the patient is awakened to his responsibilities to himself and others. His confidence in the worker and doctor being established he is started upon a course of mental hygiene consisting sometimes of months of patient reiteration of the need for daily practice of healthful habits. The social worker continues to assist with the patient's treatment through interviews and home visits and gradually becomes the bond between the patient and the doctor. Furthermore she follows the case between visits to the hospital and is thus able to have ready for the physician at each visit of the patient much information of value to him in his conduct of the case.

Convalescent and sanatorium treatment is arranged for in some cases and work secured in others. Not infrequently the treatment of these patients includes all the above care. There were 19 patients referred under this category.

A. Diagnoses.

(1) Neurosis	5
a. ? Epilepsy	3
b. Occupational neurosis	2
(2) Psychoneurosis	13
(3) Debility	1

B. Treatment.

(1) Sociotherapy	19
(2) Sanatorium	3
(3) Convalescent	2
(4) Change of environment, care away from home	1
(5) Change of work	2
(6) Social oversight	10
(7) Assistance refused	1
	19

C. Results.

(1) Improved	15
(2) Poor results	3
(3) Unknown	1
	19

4. *To get work.*—Three patients were referred for work because of its therapeutic value. The nature of their illnesses and condition made it difficult for them to secure employment from an agency.

Diagnoses.

(1) Organic peripheral disease	1
(2) Organic brain disease	1
(3) Psychoneurosis	1
	3

5. *Free treatment.*—Free treatment may range from securing admission to the clinic to raising money for an expensive apparatus. Nine patients were referred in this group.

A. Diagnoses.

(1) Organic cord disease	3
(2) Organic brain disease	5
(3) Unclassified	1
	9

B. Treatment.

(1) Salvarsanized serum	4
This requires raising sometimes $10-$20 for course of treatment.	
(2) Salvarsan	1
(3) Medicine and admission	2
(4) Apparatus, costing $20	1
(5) Hydrotherapy	1
	9

6. *Miscellaneous.*—A patient, suffering from tabes, was referred because the physician felt the man had been unfairly deprived of his insurance policy. The investigation proved otherwise and the patient was finally convinced that he had been treated leniently under the circumstances.

Another patient, a young married woman, having epilepsy, was referred because she was greatly disturbed over her mother whom she felt was being neglected in a home for aged where her family had paid $500 for her maintenance for life. The conditions were investigated and the home found to be one of questionable reputation. As the patient's brother was satisfied with the care his mother was having and refused to take legal steps the matter was dropped. This case has required much social attention as the patient's environmental conditions were poor and in need of adjustment.

7. *Steering.*—Any outside social agency may send a patient to the Social Service Department and be assured that the patient will be properly

admitted to the hospital, steered to the right physician, examined, and that the agent will receive the doctor's report as to the diagnosis made and his advice as to treatment. This coöperation between the medical social worker and the outside agency is of mutual benefit. Before the patient is referred the outside agency forwards a brief social history of the patient, and this is given to the physician before the patient is examined, and while the outside agency carries the entire social responsibility of the case. The social service worker reports upon the condition of the patient from time to time—whether he is reporting to the clinic as advised, etc.; and secures free admission and medicines if required. In the cases passing through the Neurological Department there are many instances where the outside agency must be instructed as to the specific social information needed, particularly in cases where there is a question of the patient's mental condition. There were 40 cases coming under group 7.

A. Diagnoses.

(3) Steering		40

The group designated as "old" embraces the patients who had been referred to us during previous years and with whom we are still in touch in consequence of their need of advice and help. These cases have required much attention, as their problems have frequently needed close observation and social supervision through periods extending into months. The social worker, once a friend, is called upon over and over again, for the intimate relation formed at the time of the patient's first urgent need is a tie not easily severed. The patients' knowledge of life and affairs is meagre and often confusing and their outlook is so narrow that not infrequently their future well-being depends upon their having intelligent advice on the many difficulties surrounding them, domestic and otherwise. Sometimes the solution is simple, as for instance: what may seem to them a complex family situation is in reality only the outcome of petty misunderstandings and can easily be solved by tactful measures. To expand the vision of these patients is the social worker's duty, and in her unique position and relation to them she has an unusual opportunity to teach the principles of a useful and simple philosophy of life. Her range of helpfulness extends from a smile of friendly good cheer to hours or days of extensive labor, often required before any adequate solution of the specific problem can be evolved.

IS SANATORIUM TREATMENT WORTH WHILE?

BY GERTRUDE L. FARMER, BOSTON.

Social Service Department, Out-Patient Department, Massachusetts General Hospital, Boston.

[A study of 419 phthisical patients referred during a period of six years, from January 1, 1906, to January 1, 1912, to the Social Service Department of the Massachusetts General Hospital, and sent to the State Sanatoria.]

PURPOSE.

PULMONARY tuberculosis has been the medical diagnosis of the largest group of patients referred to this department. In the first annual report of our work, 1905-1906, I wrote: "There is no other place (than Rutland) in Massachusetts where a patient can get, for four dollars a week, a dry, clear climate, free from the damp and dust of the town, expert medical supervision, plenty of good food, the discipline and psychic contagion of a large institution where everyone in sight is following the treatment. . . so hard to carry out alone at home." This seems to me to be equally true today, and we continue to try and secure this treatment for our patients. We thought it was time to make some general test of its efficacy.

At a time when the effectiveness and economy of state sanatorium care is much under discussion, we have hoped to throw a little light on the subject. Massachusetts has committed her-

self to this policy by building three other institutions in addition to the one already in existence.

We make no claim to the possibility of drawing any general conclusions from our data. The numbers found to be available are too small. This is simply a limited study of 419 individuals. The principal end we have had in view is an answer to the questions: How many of these patients are now living normal lives? How many are dragging out an existence with one foot in the grave?

METHODS.

Tracing Patients. In beginning our study we sent a letter to each patient. When no reply was received we tried to trace through relatives, private agencies, and anti-tuberculosis societies, official agencies, chiefly boards of health and town clerks. The boards of health were valuable when they employed a visiting nurse. In the case of Boston patients the out-patient department of the Municipal Hospital for Consumption and the Bureau for the Confidential Exchange of Information were of great assistance.

Difficulties in Tracing. Where other resources failed, we visited the last address, and followed up clues, until some information was obtained, or the quest proved hopeless.

The attempt to get in touch with these patients involved a great deal of work. Many of them had been seen only once. Many of them, the majority, had not been heard of since they left the sanatorium. Almost all were poor working people, who change their residence frequently, and leave few clues behind. Some have married, and in the case of women this tends to cover their tracks. Some have left the country. Many have foreign names, the spelling of which in English is problematical. Our early records contain less information than the later ones. We have no regular system of follow-up work and no facilities for it, but since 1910 we have kept a card catalogue of sanatorium cases with this study in view.

That out of a total of 419, only 20 patients remain quite untraced is owing to the untiring efforts of the workers, both paid and unpaid, assisting in this study.

GENERAL PLAN OF STUDY.

Period Chosen.—The Social Service Department started in October, 1905. When we began this study we decided to consider those patients who were admitted to and discharged from one of the state sanatoria, during the years from Jan. 1, 1906, to Jan. 1, 1912, and only those to whose going our efforts had contributed.

Why the Number Available is Small. During the six years out of a total of 8224 patients referred to us, 2564, or 31.1+%, had a diagnosis of pulmonary tuberculosis. That of these we only succeeded in obtaining state sanatorium care for 419, or 16.3+%, is due to a variety of reasons. Up to September, 1909, Massachusetts had only one state sanatorium, that at Rutland. In attempting to get a patient admitted, more difficulty was experienced than is found today. Rutland has tried to give the preference to the incipient, favorable case. Citizenship was required, and the question of finances had to be gone into. Our older records show how often a patient was held up "for lack of funds." When a patient is now unable to pay, the matter may be left to the State Board of Charity. Since 1910 we have had four state sanatoria, all under a special board of trustees, and three of them admitting all types of cases. Questions of citizenship and settlement have been much modified, and are no longer bars against admission, except occasionally in the case of an unsettled alien with an obviously poor prognosis. In cases where admission was possible, we often failed to persuade patients to go. Lack of vacancies made the interval between application and admission long, patients became discouraged, lost ground, and so were unsuitable for admission, or made other plans. These last two reasons hold good today.

The 2145, or 83.7+%, who did not go to the sanatoria were referred to tuberculosis classes, chronic hospitals, homes for incurables, anti-tuberculosis societies, etc.

We have excluded from our regular tabulation 96 patients, grouped as follows: Not considered,* 50; died at sanatorium, 21; no phthisis, 5; untraced, 20. Separate tabulation has been made of the first three groups.

Plan of Tabulation. Taking the remaining 323 patients we have grouped them according to stage on admission, noting age, length of stay, condition on discharge, and present condition. A special effort has been made to get the stage on admission and condition on discharge from the sanatorium, as it differs somewhat from that found in the hospital records.

As this is an economic study we have not entered into any discussion as to medical terms and classifications. The sanatoria have made use of the classification of "incipient," "moderately advanced," and "advanced," as given by the National Association for the Study and Prevention of Tuberculosis. They classify the discharged patients more or less according to the same authorities, as "apparently cured," "arrested," "improved," "unimproved," "dead," with the occasional use of subheadings, such as "progressive." Within a few months they have discontinued the use of the term "apparently cured" and use the much broader one of "arrested." We have used the latter term to cover all cases discharged as "apparently cured" and "arrested."

Present Condition. We have directed our attention chiefly to finding out: (*a*) the number of years that these patients have lived since

* *i.e.* remained too short a time at the Sanatorium to be instructive from the point of view of results.

discharge, and (*b*) their present condition. In the majority of cases the period noted is the winter of 1912-1913. We have classified them as "well," "alive," "dead," making use of only three terms in order to simplify the tabulation, and making these cover the following points:—

"*Well.*" Means also working or able to work, that is, the ability to lead a normal life. In the case of women we consider the occupation of housewife as a normal work condition.

"*Alive.*" Includes those too ill to work; those working but ill; those readmitted to the sanatorium and there at the time of report; those in other institutions for the tubercular; those about whom we have been unable to get any other information except that they are alive. Some of the last may be "well," which would alter our percentages.

"*Dead.*" In the case of those who have died, "present condition" means the date of death in whatever year since discharge it falls.

Medical Condition. We have not attempted to note the medical condition of these patients except as it is indicated by ability to work, and in the majority of cases this "ability" was their own opinion. To obtain an expert examination of the chest and a report on sputum would have involved great difficulties, and in many cases would have been impossible. Unless reliable it would not have been of any value. We got a few patients into the hospital for examination, but not in sufficient numbers to be of statistical benefit.

THE "NOT CONSIDERED" PATIENTS.

The state sanatoria classify as "not considered" those patients who stay a month or less. Occasionally the period has been six weeks or less. We have included under this heading those who stayed a month or less, and also some who stayed a somewhat longer period, but were discharged without a definite report on their condition.

Of the 419 patients there were 50 "not considered," or 11.9+%. The stages on admission were: incipient, 23; moderately advanced, 13; advanced, 14.

AGES ON ADMISSION (all stages).

5-10 years	0 patients
11-20 years	8 patients
21-30 years	21 patients
31-40 years	16 patients
41-50 years	5 patients
51+ years	0 patients

LENGTH OF STAY.

12 stayed 1 week or less.
19 stayed 2-3 weeks.
19 stayed 4-7 weeks.

Of the 50 patients in this group, 9, or 18%, had some complication.

STAGE I.

1 Alcoholic.	Well after 3 years.
1 Pregnancy.	Well after 6 years.
2 Neurasthenic.	1 well after 6 years. 1 alive after 5 years.
1 Old tuberculosis of knee.	Well after 6 years.

STAGE II.

1 Syphilis, morphine habitué.	Well after 2 yrs.
1 Neurasthenic.	Well after 1 year.
1 Tubercular laryngitis.	Died after 1 year.

STAGE III.

1 Tuberculosis of knee.	Died after 2 years.

Of the 23 in Stage I, 17 patients are well, 4 alive, 2 dead.

Of the 13 in Stage II, 7 patients are well, 3 alive, 3 dead.

Of the 14 in Stage III, 2 patients are well, 2 alive, 10 dead.

Totals (all stages) well, 26 patients, or 52%; alive, 9, or 18%; dead, 15, or 30%.

It will be seen that the "not considered" patients make a very good showing. Of the 23 patients admitted in the incipient stage 17 are well: 2 after 2 years, 3 after 3 years, 1 after 4 years, 1 after 5 years, 9 after 6 years, 1 after 7 years.

PRESENT CONDITION AND TIME SINCE DISCHARGE OF THE 50 "NOT CONSIDERED" PATIENTS.

	Stage I.			Stage II.			Stage III.		
	Well.	Alive.	Dead.	Well.	Alive.	Dead.	Well.	Alive.	Dead.
6 mos. or less			1						3
1 year				2		2	1		1
2 years	2		1		3		1	1	4
3 years	3			3		1		1	2
4 years	1								
5 years	1	2		2					
6 years	9	2							
7 years	1								
	17	4	2	7	3	3	2	2	10

Of the 13 admitted in the moderately advanced stage, 7 are well: 2 after 1 year, 3 after 3 years, 2 after 5 years.

These results will appeal to those who believe that the most desirable function for a state sanatorium is that of an educative establishment. If this opinion is well founded, it is fair to assume that some of these short-stay patients carried away an object lesson of great value to them in after life.

Reasons for Discharge. We made a special effort to discover the reasons for the premature discharge of these patients as we felt it would be interesting to know what induced 50 people, out of a small group, to give up what might have been their one chance of recovery from a disabling sickness. In most cases we obtained the information from the sanatorium records. We have classified these reasons as the following:

1. Insufficient evidence of tuberculosis 3
2. Too far advanced 1
3. Pregnant 1
4. Misconduct 2
5. Lack of funds 1
6. Neurasthenic 3
7. Came for education 2
8. To follow treatment at home 3
9. Dissatisfied with sanatorium 8
10. Objected to treatment 4
11. Homesick 5
12. Home or business conditions 6
13. Discouraged 1
14. Left of own accord, no reason given 3

Out of the 50, therefore, we obtained some definite information in 43 cases.

In 7 cases we could obtain no information at all. The 2 patients under 2 and 5 would not be discharged today. The 5 under 7 and 8 might be classified together as "educative cases." Nos. 11 and 12 suggest that social work in connection with the patient's home environment might have induced these 11 patients to continue their treatment.

"NO PHTHISIS" PATIENTS.

Of the 419 patients who were admitted to the sanatorium, 5, or 1.4%, were discharged as having no phthisis. These patients were all admitted as in the incipient stage. Three had other complications as follows: Exophthalmic goitre, 1; sarcoma of lung, 1; iritis (tubercular), 1. In 2 no other diagnosis was noted.

Present Condition of the 5 "No Phthisis" Patients. One died at the sanatorium, 3 are well after 2-6 years, 1 is alive after 6 years (in an institution, with advanced phthisis).

"DIED AT THE SANATORIUM."

Out of the total of 419 patients admitted to the sanatoria 21, or 5%, died before discharge. Of these 5 went to Rutland, 11 to North Reading, 3 to Lakeville, 2 to Westfield.

Stage on Admission. Moderately advanced, 7; advanced, 14.

Length of Stay. Eleven stayed 3 months or less; 4, 3-6 months; 6, 6 months or 1 year.

Complications. Of the 21 patients in this group, 8, or 38+%, had some complication other than phthisis. These were as follows: Tuberculosis of larynx, 3; of tibia, 1; of wrist and epididymis, 1; of spine, 1; of genito-urinary tract, 1; heart disease, 1.

It is to be noted that 14 of the 21 patients were admitted in Stage III. All but one had tuberculosis in another part of the body. About one-half died three months or less after admission.

AN ANALYSIS OF 323 PATIENTS DISCHARGED ALIVE FROM THE STATE SANATORIA DURING THE YEARS 1906, 1907, 1908, 1909, 1910, 1911.

The 323 patients were divided as follows on admission: Incipient, 117, or 36.2+%; moderately advanced, 147, or 45.5+%; advanced, 59, or 18.2+%. As out of a total of 323, 308 went to Rutland, while North Reading had only 60, Lakeville 39 and Westfield 12, it might have been expected that this would prove to be a study of incipient cases. The fact, however, that there were nearly 10% more of the moderately advanced helps to bear out the claim, that of all those who apply for admission to Rutland, only 33% have been in the early stages of the disease.

Living and Dead. (Total of all stages, 1912-1913.) Living, 220, or 68.1+% (106, or 90%, incipient; 98, or 66.5+%, moderately advanced; 16, or 26.9+%, advanced.) Dead, 103, or 31.8+% (11, or 9.4+%, incipient; 49 or 33.3+%, moderately advanced; 43, or 72.8+%, advanced).

An analysis of the above is given in Charts I, II and III and in the text.

AGE ON ADMISSION OF THE 323 PATIENTS.

Incipient. Total, 117 patients. 5-10 years, 0 patients; 11-20 years, 39 patients, or 33.3%; 21-30 years, 46 patients, or 39.3%; 31-40 years, 23 patients, or 19.6% (11-40 years equals 92.2%); 41-50 years, 8 patients, or 6.8%; 50 and over, 1 patient, or .85%.

Moderately Advanced. Total, 147 patients. 5-10 years, 1 patient, or .68%; 11-20 years, 28 patients, or 19.0%; 21-30 years, 61 patients, or 41.4%; 31-40 years, 38 patients, or 25.8% (11-40

years equals 86.2%); 41-50 years, 17 patients, or 11.5%; 51 and over, 2 patients, or 1.3%.

Advanced. Total, 59 patients. 5-10 years, 0 patients; 11-20 years, 1 patient, or 1.6%; 21-30 years, 28 patients, or 47.4%; 31-40 years, 19 patients, or 32.2%; 41-50 years, 6 patients, or 10.1% (21-50 years equals 89.7%); 50 and over, 5 patients, or 8.4%.

The numbers studied are too small to render any general conclusions valuable. Certain points may be noted.

Of all stages we have had only one patient in the first decade. Up to a year or so ago there was no sanatorium in Massachusetts to which children could be sent, and care for these has always constituted one of our most difficult problems. Rutland has not admitted patients under fifteen years of age. At present such children can be sent to Westfield.

Taking the sixth decade we have in all stages only eight patients. Rutland did not encourage admission over forty-five years of age.

The greatest number in the incipient and moderately advanced falls within the second, third and fourth decades. In the incipient it is 92.2+%. In the moderately advanced, 86.2+%. The maximum in both stages is in the third decade. In the incipient this is 46 cases, or 39.3+%. In the moderately advanced, 61 cases, or 41.4+%. In the advanced 89.7+% falls within the third, fourth and fifth decades, while, as in the other stages, the maximum, 28 cases, or 47.4+% is in the third decade. But the whole number of the advanced is only 59.

It will be seen that the age incidence in the incipient and moderately advanced stages agrees with the accepted theory that active phthisis is most common in the young adult, but that mechanical reasons influenced the numbers in the first, fifth and sixth decades.

LENGTH OF STAY.

The 323 patients stayed at the sanatorium as follows:—

The Incipient; 117 patients stayed a total of 2477 weeks. Average stay for each patient, 5¼ months; 35 patients stayed 3 months or less; 54, 3-6 months; 22, 6 months to 1 year; 6, 1 year or more.

Moderately Advanced; 147 patients stayed a total of 4081 weeks. Average stay for each patient, 6¾ months; 28 patients stayed 3 months or less; 47, 3-6 months; 64, 6 months to 1 year; 8, 1 year or more.

Advanced; 59 patients stayed a total of 1552 weeks. Average stay for each patient, 6½ months; 16 patients stayed 3 months or less; 22, 3-6 months; 16, 6 months to 1 year; 5, 1 year or more.

The average length of stay for all patients was about 6 months; 35, or 29.9+%, of the incipient patients stayed 3 months or less; 54, or 46.1+%, stayed from 3 to 6 months; 28, or 19.+%, of the moderately advanced stayed 3 months or less; 47, or 31.9%, stayed 3 to 6 months.

It is evident that, according to the generally accepted theory as to the length of time necessary to arrest the disease, the length of stay of these patients was too short. The fact that, notwithstanding this brief period of treatment our ultimate results are so good may be due partly to the fact that in the majority of cases, and for reasons given above, we were dealing with fairly favorable cases. Our numbers also were small. Any other conclusion would be dangerous.

So far as I know, there is no fixed period of stay required at the Massachusetts state sanatoria. I have known a patient discharged "arrested," and "with advice," after two months; another discharged "improved," and "against advice," after a year.

EXPLANATION OF CHARTS.

To show the ultimate result of our study, we have grouped the 323 patients in charts.

Chart I gives the number discharged as "arrested," "improved," "not improved," arranged according to the three stages on admission.

Chart II gives the present condition under our classification of "well," "alive," "dead." It is arranged according to the three stages on admission, and showing the numbers under each classification at different periods since discharge varying from six months to seven years.

Chart III includes Charts I and II, giving present condition under "well," "alive," "dead," in relation to the condition of discharge, and showing the numbers in certain periods of time since discharge.

DETAILS OF CHART I.

In the incipient group the largest number, 84, or 71.7%, were discharged arrested. This is 57.5% of the entire number discharged arrested, which agrees with the accepted belief as to the desirability of admission in the incipient stage. It is all the more striking when we consider that the majority of these stayed an average of six months.

In the moderately advanced group the largest number, 75, or 51.+%, were discharged improved. This is also 51.+% of the entire number discharged improved. It would seem that a longer residence than the given average of six and three-fourths months might have put many of these under "arrested."

In the advanced group the largest number, 39, or 66.1%, is also discharged improved. The largest number of the entire number discharged not improved comes in this group, 17, or 53.1%.

DETAILS OF CHART II.

"Present Condition" is the time when the report of the patient was received. In most cases it was February, 1913, but reports were received from December, 1912, up to April, 1913, and in a few cases, difficult to trace, up to November, 1913. In case of death, "present condition" is the date of death.

Time Since Discharge. In reckoning the time since discharge any part of a year under six months was not counted. Over six months was counted as one year.

Re-admissions. In case patients were admitted more than once the stage of the first admission was taken and the condition on the last discharge, excluding any admissions or discharges which came outside of the given six-year period which the study covered.

Present Condition for total of all stages: Well, 150 patients, or 46.4%; alive, 70, or 21.6%; dead, 103, or 32.1%.

Incipient Group. Of the 117 patients, 82, or 70.%, are "well"; 24, or 20.5%, are "alive"; 11, or 9.4%, are "dead."

Of the 82 patients who are "well," 3 have been discharged 1 year; 21, 2 years; 10, 3 years; 10, 4 years; 19, 5 years; 18, 6 years; 1, 7 years.

The largest numbers have been discharged 2 years (21 patients) and 5 years (19 patients).

Of the 24 patients who are "alive," 3 have been discharged 1 year; 8, 2 years; 2, 3 years; 2, 4 years, 7, 5 years; 2, 6 years.

The largest numbers have been discharged 2 years (8 patients), and 5 years (7 patients), as in group "well." Of the "alive," 10 patients are working, 2 are in hospitals, 6 are known to be "alive" but no further information obtained.

Of the 11 patients who have died, 2 lived 6 months or less after discharge; 4, 1 year; 1, 2 years; 1, 3 years; 2, 4 years; 1, 5 years.

Moderately Advanced Group. Of the 147 patients, 61, or 41.4%, are "well"; 37, or 25.1%, are "alive"; 49, or 33.3%, are "dead."

Of the 61 patients who are "well," 7 have been discharged 1 year; 15, 2 years; 13, 3 years; 7, 4 years; 10, 5 years; 8, 6 years; 1, 7 years.

The largest numbers have been discharged 2 years (15 patients) and 3 years (13 patients), but almost as many (10 patients) have been discharged 5 years.

Of the 37 patients who are "alive," 8 have been discharged 1 year; 13, 2 years; 6, 3 years; 1, 4 years; 4, 5 years; 4, 6 years; 1, 7 years.

The largest number have been discharged 1 year (8 patients), and 2 years (13 patients). Of the "alive," 17 patients are working, 14 are in hospitals.

Of the 49 patients who are dead, 10 lived 6 months or less after discharge; 13, 1 year; 8, 2 years; 12, 3 years; 3, 4 years; 2, 5 years; 1, 6 years.

Advanced Group. Of the 59 patients, 7, or 11.8%, are "well"; 9, or 15.1%, are "alive"; 43, or 72.8%, are dead.

Of the 7 patients who are "well," 2 have been discharged 1 year; 2, 2 years; 1, 3 years; 2, 5 years.

Of the 9 patients who are "alive," 3 have been discharged 1 year; 4, 2 years; 1, 3 years; 1, 5 years. Of the "alive," 3 patients are working, 2 are in hospitals.

Of the 43 patients who have died, 17 lived 6 months or less after discharge; 15, 1 year; 6, 2 years; 2, 3 years; 1, 4 years; 2, 5 years.

DETAILS OF CHART III.

Incipient Group. Of the 117 patients, 84, or 71.7+%, were discharged arrested. Of these, 66, or 78.5+% are well; 17 have been discharged 2 years (or less); 17, 3-4 years; 32, 5-7 years.

Fifteen, or 17.8+%, are alive; 6 have been discharged 2 years (or less); 2, 3-4 years; 7, 5-7 years.

Three, or 2.5+%, are dead; 2 lived 2 years (or less) after discharge; 1, 3-4 years after discharge.

Thirty-one, or 26.4+%, were discharged improved. Of these, 16, or 51.6+%, are well; 8 have been discharged 2 years (or less); 1, 3-4 years; 7, 5-7 years.

Nine, or 29.0+%, are alive; 5 have been discharged 2 years (or less); 1, 3-4 years; 3, 5-7 years.

Six, or 19.3+%, are dead; 3 lived 2 years (or less) after discharge; 2, 3-4 years; 1, 5-7 years. Two, or 1.7+%, were discharged not improved. These both died 2 years or less after discharge.

Moderately Advanced Group. Of the 147 patients, 59, or 40.1+%, were discharged arrested. Of these, 33, or 55.9+%, are well; 13 have been discharged 2 years (or less); 12, 3-4 years; 8, 5-7 years.

Eighteen, or 30.5+%, are alive; 10 have been discharged 2 years (or less); 5, 3-4 years; 3, 5-7 years.

Eight, or 13.5+%, are dead; 2 lived 2 years (or less) after discharge; 5, 3-4 years; 1, 5-7 years.

Seventy-five, or 51.0+%, were discharged improved. Of these 29, or 38.6+%, are well; 9 have been discharged 2 years (or less); 8, 3-4 years; 12, 5-7 years.

Fifteen, or 20.%, are alive; 10 have been discharged 2 years (or less); 4, 3-4 years; 4, 5-7 years.

Thirty-one, or 41.3+%, are dead; 20 lived 2 years (or less) after discharge; 9, 3-4 years; 2, 5-7 years.

Thirteen, or 8.8+%, were discharged not improved. Of these 1, or 7.6+%, is well 5-7 years

after discharge. Two, or 15.3+%, are alive; 1 has been discharged 2 years (or less); 1, 3-4 years.

Ten, or 76.9+%, are dead; 9 lived 2 years (or less) after discharge; 1, 3-4 years.

Advanced Group. Of the 59 patients, 3, or 5%, were discharged arrested. Of these, 2, or 66.6+%, are well; 1 has been discharged 2 years (or less); 1, 5-7 years.

One, or 33.3+%, is alive 2 years (or less) after discharge.

Thirty-nine, or 66.1+%, were discharged improved. Of these, 5, or 12.8+%, are well; 3 have been discharged 2 years (or less); 1, 3-4 years; 1, 5-7 years.

Seven, or 18.3+%, are alive; 5 have been discharged 2 years (or less); 1, 3-4 years; 1, 5-7 years.

Twenty-seven, or 69.2+%, are dead; 22 lived 2 years (or less) after discharge; 4, 3-4 years; 1, 5-7 years.

Seventeen, or 28.8+%, were discharged not improved. Of these, 1 or 5.8+%, is alive 2 years (or less) after discharge. Sixteen, or 94.1+%, are dead, all 2 years (or less) after discharge.

It is of interest to note that in Chart I the per cent. of patients discharged "arrested" in the incipient group, 71.7+%, nearly agrees with the per cent. found to be "well" in Chart II, 70.0%. Whether or not these "arrested" patients are the same who are now "well" is shown in Chart III, where it is found that of the total discharged "arrested," 78.5+% are now "well." An "arrested" condition on discharge carries with it a good prognosis, and in our 323 patients this prognosis was realized. The per cent. of those discharged "improved," 26.4+%, coincides with those now "alive," 20.5+%. In Chart III it is found that of those discharged "improved" only 29.0+% are "alive." This indicates that of those discharged "improved," the larger number are in other groups; 51.6+% are found in "well," and 19.3+% are dead,—a very favorable result in "improved" cases. The per cent. of those discharged "not improved," 1.7%, and of those now "dead," 9.4%, is not similar, which is as we might expect, as a certain number of those discharged "arrested" or "improved" would be found to be "dead" either because they were not as well as was thought, or because they had not been able to have the care they still needed.

In the moderately advanced group there are 40.1+% discharged "arrested" and 41.4% now "well." Chart III shows that of the "arrested" 55.9+% are now "well"; a smaller per cent. than in the incipient group, as one might expect, since it is harder as the disease advances to predict the outcome. For the same reason the per cents. of those "improved" and "not improved" do not agree with the per cent. "alive" and "dead." An increased variance is found in the advanced patients.

CHART I.

CONDITION ON DISCHARGE OF THE 323 PATIENTS.

Stage on Admission.	Arrested	Improved.	Not Improved.
I	84 or 71.7+%	31 or 26.4+%	2 or 1.7+%
II	59 or 40.1+%	75 or 51.0+%	13 or 8.8+%
III	3 or 5.0+%	39 or 66.1+%	17 or 28.8+%
Total	146 or 45.2+%	145 or 44.8+%	32 or 9.9+%

CHART II.

PRESENT CONDITION OF THE 323 PATIENTS CLASSIFIED AS: WELL, ALIVE, DEAD, AND SHOWING THE TIME SINCE DISCHARGE.

Stage.		6 Mos. or Less.	1 Yr.	2 Yrs.	3 Yrs.	4 Yrs.	5 Yrs.	6 Yrs.	7 Yrs.	Total.
I	Well		3	21	10	10	19	18	1	82 or 70.0+%
	Alive		3	8	2	2	7	2		24 or 20.5+%
	Dead	2	4	1	1	2	1			11 or 9.4+%
II	Well		7	15	13	7	10	8	1	61 or 41.4+%
	Alive		8	13	6	1	4	4	1	37 or 25.1+%
	Dead	10	13	8	12	3	2	1		49 or 33.3+%
III	Well		2	2	1		2			7 or 11.8+%

SOME HUMAN DOCUMENTS.

Tabulations and percentages have some statistical value and furnish quotable material. They are rather dry reading. When obviously unstudied, and intelligent, letters from patients give the most valuable as well as the most interesting information. Here are some extracts from those received by us in answer to our enquiries. I give a few data on each case as they were when first seen by us and then the extracts in the writer's own words, changing names and places.

N. K., a married women, 39 years of age, six children. A moderately advanced case, at Rutland three months. Discharged, arrested 1907. Under observation in our tuberculosis class before and after going to the sanatorium. Lost sight of for three years. December, 1912, she writes, "I am in the best of health at present, I think I could not feel any better, my weight is 210 pounds at present." This patient was always heavy, 180 pounds when first seen.

A GOOD STUDENT.—T. T., single, 18 years of age. An incipient case, at Rutland, 1907, four months. Discharged arrested. Lost trace of for nearly five years. December, 1912, he writes, " . . . from a slim, haggard-looking human skeleton I have been transformed at the Sanatorium to a ruddy, active citizen. Since leaving the sanatorium I have entered . . . University and graduated with the degree of LL.B. I did not think it expedient to let my high school education go to naught. I paid my tuition by giving private lessons in English, to men of foreign birth. . . . I have never been confined to bed on account of my physical condition. Have retained every ounce of the 20 pounds gained at Rutland. This is perhaps due to the fact that sleep 365 days a year in the open, do not smoke nor drink and lead a regular life. I do not cough, except a little when I rise. I sleep soundly, eat well. Of course I am not a strong man. I am rather short-winded. To remedy this I walk slow and do not over-exercise."

THE BEFORE AND AFTER MAN.—N. E., single, 23 years of age. An incipient case, at Rutland about six and one-half months. Discharged arrested 1907. Not seen by us after admission. Six years after discharge he writes, " . . . was glad to know you people are interested in my health . . . am in the best of health at present, ... thanks to my dear wife I have been able to follow the rules of the Sanatorium, chest baths, etc. Four years after leaving the Sanatorium we came to Colorado. I work at my old trade of tailoring, have managed to keep up my weight . . . don't cough but do raise in the A.M. I send you a photo which I had taken in Rutland and one I had taken here in front of my house." The photographs show in the first a cadaverous, big eyed young man, the second a smiling, self confident fat man standing in front of a frame cottage.

A PERSEVERING WORKER.—T. D., single, 27 years old. An incipient case, at the Sanatorium about eight months. Discharged arrested. March, 1912, writes " . . . after leaving the Sanatorium in February I go back to my old work (in a factory) and I commence to lose weight again. So I go to Canada. I do not do much work that summer but I kept on with the treatment, sleeping out of doors and taking exercise. (sic) That winter I work in the woods, but don't forget the Sanatorium rules. Last spring (1912) I come to New Hampshire I get employment on large farm. I didn't have any idea I could hold my position. I stated my case to my employer, and he bought a tent for me. I work hard all summer and did not lose weight. I gain about 30 pounds when at the Sanatorium and I have 25 of that now. I must tell you I never work on a farm before. I had to learn to handle horses and operate the up-to-date machinery. I heard from one of my neighbors that my boss says I do as good work as any man he has. I tell you this to show you what the Sanatorium did for me. This is a fine country for T. B. We have three foot of snow at present and this morning at 6 A.M. it was 24 below zero. If more of the rested T. B. cases would come here instead of staying round the city it would do them more good."

F. P., single, 29 years old. A moderately advanced case. A student at college when first seen. Nine and one-half months at the Sanatorium, discharged arrested. Not seen again by us. January, 1913, writes " . . . After leaving the Sanatorium I went to Colorado for a year to find profitable employment, to get the benefit of the climate, and to make a home. But one had better be sure of some employment and not trust wholly to good fortune to land him in a job when he arrives there, for there are few industries . . . and more half-well people willing to work for next to nothing, than you can imagine . . . I found it difficult, impossible, to get employment of any kind immediately and I had no course open except to return East . . . I am living in . . . with my wife and child . . . They and I have been perfectly well. I, since I left the Sanatorium, have had nothing to remind me of my former trouble. Sleep always with open windows and have had no cause for calling in, or upon, a doctor." This patient wrote us an eight-page letter full of his experiences since leaving the Sanatorium.

A TEMPERANCE LECTURE.—As a contrast to the above reports take the case of K. D., married, six living children, five dead children. First seen by us June, 1910. The record says, "drinking considerable, chewing five plugs of tobacco a day." Admitted to North Reading August 13, 1910. An advanced case. Discharged October 21, 1910, "improved, against advice." Patient told us he wanted to go to work. We expended much energy in the effort to reorganize the family situation. The burden of a drinking, consumptive father was too heavy. Admitted to Lakeville December 28, 1910. Not working in meantime. The wife reported that patient could always get something to drink. Discharged from Lakeville July 28, 1911, "improved, for misconduct." The patient was reported to have choked an orderly. The social service worker records "evidently an obstructionist." March, 1913, the wife reported to the visitor that the patient had been arrested for drunkenness and committed to the State Farm at Bridgewater. From there we found he had been sent on September 4, 1912, to the Prison Camp and Hospital at West Rutland, admitted as a moderately advanced case. Discharged arrested on August 16, 1913. Had been working

on the farm for sometime previously. This man has spent 21 months under State care; nine months and one week at a sanatorium, almost a year at the Tuberculosis Prison Hospital and Camp. I think the superintendents of the State Sanatoria would tell us that the alcoholics make the poorest patients, do the worst, and give the most trouble.

A BORN FIGHTER.—C. T., single, 41 years old. Admitted August 22, 1910. A moderately advanced case. Remained as a patient 14 months. After 13 months he writes: "It is strange to me I have never had a sick day or a temperature since I came, but still I don't seem able to shake the germs. It's a funny disease. But it's a long lane that has no turn." Discharged October 28, 1911, and remained at the Sanatorium to work. Worked there about 10 months when he left to try for work elsewhere. October 11, 1912, writes, "last August I left the Sanatorium to try for work in a mill, only just got a job. On going to work yesterday morning raised a little blood and last night had a sweat. Have worked just one day. I have no money and know no one that can give me any. Do you wonder that I am discouraged?"

This patient was later admitted to Westfield in the autumn of 1912. May, 1913, he writes from the sanatorium: "I went to work here May 24. I have charge of the boys' camp, 41 beds, half of them under 10. A boiler factory cannot boast of more noise. I like it first rate, the position, I mean, not the noise. I bathe about one-half the children, those under 10, take care of the laundry, make them keep tidy, get them to meals and to school."

LEARNT HER LESSON WELL.—W. T. is a good example of the use of the Sanatorium for the purpose of education. Married, 38 years old, five children. Under observation in our tuberculosis class both before and after going to the sanatorium. Was at Rutland about five weeks, an incipient case. Discharged "arrested" 1907. "Left because husband was tired of doing without her." Not seen for three to four years. December, 1912, she came to the hospital and reported. "My health is excellent. I have slept out of doors since leaving the Sanatorium and carried out the treatment."

FREQUENT RE-ADMISSIONS.—G. T., single, 22 years old, admitted first as incipient case, but with tuberculosis of the spine. Re-admitted five times. These are the dates of admission and discharge:

1. Ad. October 20, 1908, incipient.
   Dis. October 23, 1909, "arrested."
2. Ad. June 28, 1910, moderately advanced.
   Dis. October 17, 1910, "improved."
3. Ad. June 1, 1911, moderately advanced.
   Dis. November 1, 1911, "improved."
4. Ad. June 7, 1912, moderately advanced.
   Dis. October 1, 1912, "arrested."
5. Ad. June 11, 1913, incipient.
   Dis. October 1, 1913, "arrested."

The fourth and fifth admissions do not fall within our tabulations. I give them here to complete the illustration.

This patient spent 28 months at the Sanatorium in all. Was sent South in the winter by a philanthropic person interested in his welfare and returned to the Sanatorium as to a summer resort. The lung lesions were comparatively slight. It might be questioned whether it was wise to use a bed at the Sanatorium so long for such a case.

"DEMORALIZED."—X. C., married, 29 years of age. Was at Rutland between three and four months, an incipient case with a very good prognosis. Discharged, "arrested," in the summer of 1909. When he came to the hospital in answer to our request he reported that he had been afraid to work since discharge, except on part time occasionally. The physician said he was in excellent condition. He is a big stout man. This patient may be constitutionally lazy, but did not so impress us. He seemed relieved and cheered when the doctor prescribed work and plenty of it.

COMMENTS.

The number of cases of pulmonary tuberculosis throughout Massachusetts has been computed at 10,000-12,000 yearly. Up to 1909 there were 350 beds available at a state sanatorium. This number has been increased until now there are about 925, or provision for 9.2+% of the phthisis cases, taking the minimum number of 10,000. We secured state sanatorium care for 419, or 16.3+%, of the 2564 phthisis patients referred to us during the six-year period. It is apparent that the state sanatoria have, so far, played a relatively small part in caring for individuals. Their educative value cannot be computed. The discharged patients have carried the gospel of hygienic living to thousands. The day seems still distant when state care for the phthisical patient will be so organized that private societies can withdraw from the field. Only in few, if any, localities is municipal work able to fill the gap. The state should encourage and help to standardize all forms of private effort in order to secure the maximum of result with the minimum of duplication. Private dispensaries, tuberculosis classes, anti-tuberculosis societies, private sanatoria, day camps: we need them all. How else could we have even attempted the care of our 83.7+%?

We should like to make a study of a group of the patients put on the waiting lists for state sanatorium care and not admitted. They would offer about the same sort of material as our 419 patients. Many of them remained at home, some under the care of private physicians. A later study of patients discharged from the four state sanatoria would be valuable and should be done in two or three years. It would be a fairer test, as the cases would be less selected than our 419.

I regret that we did not attempt to obtain more data about the 419 patients. For example: What proportion of these patients had a family history of tuberculosis? How many returned to their former environment, both as to home and occupation? With the exception of the dangerous trades, there is a growing tendency to encourage patients to return to their former work, and to concentrate social effort on the regulation of the other sixteen hours a day. There is not much statistical evidence as to the comparative merits of these plans.

We thought it would be of interest to find out how many of the 323 patients had some other disease, or tuberculosis elsewhere than in the lungs. We disregarded certain illnesses, as chronic rhinitis and chronic laryngitis, also "debility" and pleurisy. In only 50 patients, or 18.5+%, could we find any evidence of serious complication, although we searched both the sanatorium and the hospital records. As the autopsy table furnishes proof that the great majority of cases of phthisis have tuberculosis elsewhere in the body, it is fair to assume that these 419 patients did not receive a thorough physical examination.

In attempting a study like this, one naturally turns to work along similar lines both for inspiration as to methods and comparison of results.

The difference of the methods employed and the numbers and class of patients dealt with makes any real comparison difficult and misleading. We found the work of Dr. Noel Bardswell,[1] Dr. H. M. King,[2] and Dr. A. P. Francine,[3] especially helpful, and I take this opportunity of acknowledging our obligation to these gentlemen.

Dr. King and Dr. Bardswell, for the most part, did not deal with indigent patients, and they all had the great advantage of a yearly report in compiling their statistics. Their analysis was based, in great part, upon medical findings, and so is more valuable. Our ultimate results, however, are somewhat similar. Dr. Bardswell says his statistics show that 50% of his patients will be in good health 4-9 years after discharge. Dr. King that 28.33% were in a satisfactory condition of health 6-9 years after discharge; only 25% of these were indigent patients. Dr. Francine shows that 51.85% were in good health 4 years after discharge; these were all indigent patients. We found 46.4+% of our indigent patients leading normal lives from 6 months to 7 years after discharge, and 23.5+% 4-7 years after discharge.

Many others have been engaged on this study besides myself. I want particularly to acknowledge my indebtedness to the following: Dr. R. C. Cabot, without whose encouragement and financial aid the work could not have been undertaken; Mrs. W. A. Hinton, and the unpaid workers who did most of the visiting; Miss Ethel Chase, to whom I owe a particular debt of gratitude. She has freely given much time to compiling and arranging the statistics, and in helping me to present the results of our study. I could not have carried the work to completion without her assistance.

ILEAL STASIS.

Report of Thirty-three Cases.

By Gerald Blake, M.D., Boston,

Assistant Physician to Out-Patients, Massachusetts General Hospital; Assistant in Medicine, Harvard Medical School.

From the great amount of bismuth x-ray work done on the gastro-intestinal tract during the last few years, in normal cases as well as in those showing symptoms, certain standards have been established which are now generally accepted. It is found that the small intestine normally empties itself of bismuth in less than nine hours after the taking of bismuth by mouth. The presence of bismuth in the ileum more than nine hours after ingestion indicates a delay in the passage of the intestinal contents which is called ileal stasis. This is a functional disorder and may appear as the only abnormal condition present in the case. As a rule, however, it is a symptom or sign of some underlying pathological change, *e.g.* adhesions, inflammation or obstruction.

Analysis of the first 33 cases which showed an ileal stasis of nine hours or more by bismuth x-ray examination at the Massachusetts General Hospital gives results which seem of sufficient interest to warrant publication. As will be seen, the cases were subjected to examination for a variety of conditions—the diagnosis in those cases not operated upon being that given at discharge from the hospital after careful study in the wards. It should be borne in mind that in the great majority of the cases ileal stasis was but one of many abnormal conditions found at x-ray examination. Diagnosis made in this series of 33 cases was as follows:

Adhesions, 8,—

with intermittent hydronephrosis	1
with enteroptosis	1
with cerebral syphilis	1
with congenital syphilis	1
question of adhesions	1
with chronic appendicitis	1*
adhesions	2

Appendicitis (chronic), 4,—

with lead poisoning	1
with gastric neurosis	1
with adhesions around gall bladder	1*
chronic appendicitis	1*

Cholelithiasis, 2,—

with question of chronic appendicitis	1
cholelithiasis	1*

* Operated.

Constipation, 3,—	
with gastric ulcer	1
constipation	2
Chronic hepatitis with pigmentation	1
Debility, 1,—	
with gastric neurosis	1
Duodenal ulcer, 1,*—	
Neurosis, 2,—	
with menopause,	1
neurosis	1
Neurasthenia,	1
Ptosis, 4,—	
visceroptosis	2
with cystitis and senility	1
gastroptosis and debility	1
Epigastric and inguinal hernia	1*
Renal calculus and pyelitis	1*
Stricture Tb. of ileum	1*
Tabes dorsalis	1
Tb. peritonitis	1*
Stricture descending colon	1

Five of the above cases had been operated upon in the past for appendicitis as follows:

Adhesions.
Adhesions and intermittent hydronephrosis.
Cholelithiasis.
Pelvic adhesions with congenital syphilis.
Renal calculus and pyelitis.

Five of the cases showed ileal stasis of twenty-four hours or more as follows:

Man, aged 53—diagnosed chronic appendix and adhesions around gall-bladder.*
Woman, aged 21—constipation.
Woman, aged 24—gallstones. Question of appendix.
Woman, aged 29—gastric ulcer.
Woman, aged 42—neurosis.

This last case showed a stasis of 72 hours. The symptoms were not marked, however, and operation was not considered advisable.

Thirteen of the cases (40%) were in men; the ages ranging between 20 and 53, of which 6 or 48% were between the ages of 20 and 30.

Twenty of the cases (60%) were in women; the ages ranging between 21 and 63, of which 7 or 35% were between the ages of 20 and 30.

The series of cases divides itself naturally into certain groups which may be described as follows:

Group 1. Those cases in which ileal stasis is the only abnormal condition found. (Diag. constipation, 2 cases.)

Group 2. Those cases in which there is obstruction or inflammation at or beyond the lower end of the ileum; a group in which the condition of ileal stasis is due to obvious mechanical causes. (Diag., adhesions, 8; appendicitis, 4; tb. peritonitis, 1; tb. strict. ileum, 1; stricture descending colon, 1,—15 cases.)

Group 3. Those cases in which there is loss of nerve or muscle tone in the small intestine, together with the cases of ptosis which are largely due to lack of tone in certain structures or to faults in posture. (Diag., ptosis, 4; neurosis, 2; neurasthenia, 1; tabes dorsalis, 1; debility, 1,—9 cases.)

Group 4. Those cases in which there is delay in emptying the stomach with an accompanying delay in the passage of contents from the small intestine. (Diag., duodenal ulcer, 1; gastric ulcer with constipation, 1,—2 cases.

Group 5. Those cases in which the primary pathological condition seems distinct from the condition of ileal stasis; in which he may consider ileal stasis merely coincident. (Diag., cholelithiasis, 2; chr. hepatitis, 1; epigast. and inguinal hernia, 1; renal calcu. and pyelitis, 1,—5 cases.)

Groups 2 and 3 require no comment, the condition itself being sufficient to cause ileal stasis.

Group 4 suggests the type of case written about extensively by certain observers, notably Lane and Jordan in England, who believe that the pull exerted by the sagging loaded terminal loop of the ileum on the root of the mesentery causes a partial obstruction of the duodenum and resulting delay in the passage of food from the stomach together with gastric symptoms. It is noticeable in the cases of pure ileal stasis that the symptoms resemble closely those of certain stomach disorders—notably hypersecretion and hyposecretion. I have included in this group, however, only cases which appear to have a definite pathological lesion in the stomach or duodenum so that it seems fair to assume that the stomach condition is the important factor and the ileal stasis shown is a result of delay in the passage of contents from the stomach. This cannot, however, be conclusively demonstrated by the small number of cases reported in this series; and the fact that ileal stasis *per se* offers similar gastric symptoms makes the consideration of the type of case worthy of closer analysis when a large number of results is available.

What relation, if any, there is between the primary pathological condition in Group 5 and the accompanying ileal stasis is not clear. Certain of these cases would possibly come under Group 3 if careful analysis were made into the question of loss of nerve or muscle tone—ptosis—etc. The others show no probable relationship and are probably examples of a comparatively large group in which ileal stasis is not a prominent cause of symptoms and is merely coincident.

The symptoms of the two cases of simple ileal stasis were chiefly referred to the stomach—the most marked symptom being distress in epigastrium within one hour after meals. There was moderate constipation in both cases.

A brief review of the commoner symptoms found in the cases is of interest:

* Operated.

		Cases.	%
Constipation		19	57
Constipation alternating with diarrhea		3	9
Gas (in epigast. within one hour p. c.)		16	48
Pain		26	78
Epigastric pain		19	57
Pain, rt. iliac fossa		4	12
Pain in left lower quad.		2	6
Pain in both flanks		1	3
Nausea		6	18
Vomiting		15	45
Stomach contents	High acidity	8	24
	Normal acidity	8	15
	Low acidity	6	18
Diarrhea		1	3

Of gastric contents analysis only one was markedly high and one markedly low. The others were within what may fairly be called high normal and low normal limits. No case showed food residue in the fasting stomach.

The two most common symptoms found in this series of cases were constipation and epigastric pain or distress shortly after meals. Constipation is a natural cause or sequel of the condition of stasis. The relative frequency of the epigastric pain immediately after meals may be accounted for either by the constipation or the theory that ileal stasis produces some degree of obstruction in the duodenum by the pull of the loaded sagging ileum on the root of the mesentery. The nausea and vomiting are probably in relation to the amount of obstruction thus caused and subsequent change in the stomach function. It is fair to say that the degree of variation in the results of analysis of the gastric contents is scarcely proportionate to the severity of the gastric symptoms.

Noticeable is the relatively small number of cases showing alternating constipation and diarrhea which might be expected to occur where there is much fermentation of food residue in the small intestine.

TREATMENT.

Medical. The medical treatment resolves itself into an attempt to restore the inefficient bowel to its normal function. Relief of constipation over a long period of time may of itself be a curative measure, and this has been best accomplished by the use of some of the mechanical agents for moving the bowels, preferably, Russian oil in ½ oz. doses two or three times a day, or Agar Agar in 2 dram, doses T.i.d. or both together, with a diet aimed at relief of constipation and general hygienic and tonic measures to strengthen the weakened tissues.

Mechanical. It is noticeable in x-ray examinations of these cases that the last loop of the small intestine, as a rule, runs up from the pelvis and joins the large intestine at an acute angle rather than at a right angle. Some form of abdominal support is therefore often desirable to aid in holding the small bowel more nearly up in normal position. A webbing belt or swathe passing around the body between the crests of the ilia and greater trochanters of the femurs has been found to be of value. Faults in posture should be corrected by appropriate exercise and apparatus. Rest in a recumbent position after meals is of value as aiding the stomach and intestine to empty themselves, and such exercise as is indicated to strengthen the abdominal muscle and make a firm abdominal wall will aid in holding the small intestine in place.

Surgical. Should these methods prove inefficient and the nerve element be not considered too great a factor operative interference is advisable in the individual case. Where the condition is an aggravated one—where a band or kink is obvious—or where there is obstruction from other causes not to be remedied by non-surgical measures an operation should be done and at as early a date as possible. In the cases of long standing where no obvious obstruction is present but where the symptoms are marked and do not respond to medical or mechanical treatment the resort to surgical interference—short circuiting the large intestine, etc., will often establish efficient drainage of the small bowel and effect relief of the underlying condition.

CONCLUSION.

In this series of 33 cases the following facts are noticeable.

1. Ileal stasis is found,—(1) as a pathological entity; (2) as a symptom of other pathological conditions; (3) as a coincident condition in other diseases to which it is not apparently related.

2. Constipation and epigastric pain soon after meals are the commoner symptoms.

3. The stomach contents analysis is of little or no value in making a diagnosis.

4. Two cases only were of the typical primary ileal stasis type—those diagnosed constipation—although the cases of neurosis and debility (five in number) might be considered as possibly belonging to this type.

5. No case of Lane's kink was found.

6. The treatment is by choice relief of constipation by Russian oil or Agar Agar or both, together with hygienic and tonic treatment, mechanical support of ptosed structures and correction of faulty posture, surgical operation.

7. Diagnosis of the condition is made by bismuth x-ray examination.

I am indebted to Drs. Edsall, Cabot, Smith, Lord, Lee, Hewes, Williams, Codman and Whittemore for permission to use the clinical records of their cases; and to Drs. Dodd and Holmes for permission to use the x-ray records and assistance in the observation of cases.

Medical Progress.

FIFTH REPORT OF PROGRESS IN ORTHOPAEDIC SURGERY.

BY ROBERT B. OSGOOD, F.A.C.S.; ROBERT SOUTTER, F.A.C.S.; HERMANN BUCHOLZ, M.D.; HARRY C. LOW, M.D.; MURRAY S. DANFORTH, M.D.

(*Concluded from page 389.*)

BONE AND JOINT SURGERY.

Experimental. Cotton and Loder[30] have undertaken careful animal experimentation in order to determine which of the two prevailing theories as to the fate of bone grafts is correct. The first theory is that the bone graft is retained without essential change and that it becomes an active centre of growth. The second theory is that the transplanted bone is replaced by a newly formed bone and that the graft is merely a trellis, taking no active part in the repair. They have found that the transplanted bone becomes rapidly fixed by adhesions and that there is a change in every portion of the bony tissue. The bone trabeculae disappear and new bone substance is laid down in the centre as well as in the periphery.

Haas[31] has studied the regeneration of bone from periosteum (rabbits, dogs, and cats), taking his experimental tissue from the ribs. He concludes that the periosteum has the power of regenerating bone and that blood clot enhances this power. He has found that regeneration may occur in the absence of pre-existing bone. He has never in his experiments found bone regeneration in the absence of periosteum.

Axhausen's[32] experiments with the transplantability of joint tissues are interesting and seem to agree with the work of Cotton and Loder as far as the bone portion of the transplant is concerned. He used the lower end of the femur in rats and the patella or pieces of the epiphysis of the femur in rabbits, transplanting these into the subcutaneous tissue of the back of the same animal, making his subsequent examination at periods varying from 3 to 100 days. He believes that in these animals his researches have shown (1st) that bone tissue is not transplantable in a histological sense, and that it undergoes an aseptic necrosis; (2nd) that medullary tissue is transplantable and that joint cartilage is transplantable both histologically and practically; (3rd) that epiphyseal cartilage is transplantable in a histological sense but not enough for practical purposes.

(Ed. Note: The experiments of Soutter at the Harvard Medical School confirm Axhausen's finding in relation to the transplantation of cartilage in dogs.)

Henle[33] reports six cases in which he has employed a method somewhat similar to the Lange method of local splinting of the diseased area in tubercular caries of the spine, except that he employs two grafts of bone removed from the tibia instead of the tinned metal wire splints of Lange. These grafts are placed one on either side of the freshened spinous processes or, where there is a considerable kyphos, on to the laminae. The bone is sutured in place by fixing it to the inter or supra spinal ligaments. He keeps his cases in plaster from two to six months.

Two remarkable cases of joint transplantation are reported by Tuffier,[34] one in a man of 23 who had had an ankylosed elbow for two years. The ankylosed joint was resected and a tibio tarsal joint removed from an amputation in a woman was sutured in place. This case is now 18 months old and the arm is said to functionate well. The x-ray of the transplanted joint seems to show no change in its contours or structure. His second case was that of a man with advanced tuberculosis of the elbow, and the same type of graft was used in this case, having been recovered from a leg amputated five days previously and kept in cold storage. He reports that this joint also has shown no change since transplantation and that the function has been excellent for fourteen months.

Taylor[35] still employs his yellow wax, (one part with 5-10 parts lanoline, melting at 130° F., and sterilized in an autoclave thirty minutes), in the treatment of ankylosed joints, reporting seven cases of fibrous ankylosis in which he has regained motion. We have not seen reports of the use of this original method by other surgeons.

Murphy's[36] report of some 16 cases of arthroplasty by his method of pedunculated and occasionally free fascia flaps includes nearly all the joints of the body except the shoulder, and the results appear surprisingly good.

(Ed. Note: Not the least valuable portion of the article is a plea for the prevention of ankylosis in these infected joints by rational methods of preventive treatment. Far too many acute non-tubercular joints are fixed by splints or plaster bandages and allowed to remain fixed until firm fibrous ankylosis has occurred. We wish again to state our conviction that acute joints which do not rapidly quiet down under rest should be opened, washed out, and sewed up, and that passive motion in all should be begun at the very earliest moment. The results by and large in the most important joints of the hip and knee from arthroplastic operations are still too uncertain for any neglect of these preventive measures.)

The accurate pathology of "snapping hip" has been so often doubtful that a case reported by Binnie[37] represents an important contribution to the subject. Binnie's patient, when carrying a heavy weight or leaning to the right, felt a rubbing over the right iliac crest and on

jumping or suddenly twisting his body he often felt a sharp audible click as if the hip was dislocated. At operation a rolled up fold of fascia along the anterior border of the gluteus maximus was found, which fold slipped over the greater trochanter. By suturing this to the vastus externus the symptoms were relieved.

Magunson[38] has continued his experiments on dogs in relation to the lengthening of shortened bones of the leg by operation, employing carefully devised ivory screws. In the dog the femur can be lengthened ⅜ to ½ an inch without injury to vessels or nerves, and in man he believes 2 to 3 inches might be safely gained. He finds the ivory screws are later absorbed.

SCOLIOSIS.

Perhaps no question in orthopaedic surgery is more important at present than the question of how much may be expected in the way of immediate and permanent correction of the fixed scoliotic curves, by the newer methods of applying plaster jackets in flexion devised by Abbott and Forbes. It may be of interest, therefore, for us to report the opinion of men who have had experience with the method.

Vulpius,[39] in April, had used Abbott's method in 25 cases, and came to the conclusion that with the use of Abbott's table and a correct technique, over-correction is possible in certain cases, and a degree of correction may be obtained which heretofore was impossible. He considers that pressure sores are dangerous and warns against a too early giving up of the plaster cast. He believes that it is still impossible to offer a conclusive judgment as to the permanence of the method.

Joachimsthal[40] has tried the Abbott method in thirty-six patients, varying in age from 8 to 20 years. All of them had fixed curves and had been treated previously without marked results. He finds the total curvatures and those in which the dorsal curve predominates as most amenable. He considers the immediate results surprisingly good in regard to the shape of the thorax, but they are to be explained to some extent, he thinks, by the making of a compensatory curve of the lumbar spine. He still feels somewhat sceptical concerning the final results.

Kleinberg[41] in America has had a very large number of cases (85) under treatment by the Abbott method. He has followed some 40 of these closely and reports 31. He considers the method severe, necessarily prolonged, but capable of giving good results, especially in the milder cases. Of these 31 cases, 10 gave up the treatment after two months. He believes certain cases may be overcorrected, but is not sure that relapses will not occur. He thinks that many can be put in a better attitude, perhaps by the development of compensatory curves.

Whitman[42] believes that Abbott has shown a new surgical principle of treatment that will lead to a great advance in correcting the deformity of scoliosis. He considers that Abbott himself is rather optimistic and he appreciates the limitations of the method, yet he thinks it will be effective in certain cases.

Stern[43] from his experience with a few cases considers Abbott's method the best we have at present.

"*Sciatic Scoliosis.*" Bucholz has made a very thorough study of the phenomenon called sciatic scoliosis. There has been much literature on the subject, especially in Europe, but comparatively little light has been thrown on the etiology or the treatment. Bucholz has selected 174 cases showing deviations of the spine from 761 lesions of the sacro lumbar and sacro iliac regions and has carefully analyzed them. He concludes that not one peculiar, but many, lesions may cause a deviation of the spine, sometimes to the right, sometimes to the left, sometimes total, sometimes with compensatory curves, sometimes changeable by manipulation from one side to the other. He has demonstrated cures in certain obstinate cases by a special method of recumbency with traction and hyperextension of the affected leg. In other cases massage, exercises, and manipulation are indicated, and in others fixation.

(Ed. Note. The anatomical study of the region of the fifth lumbar and sacrum is of utmost importance in these severe back cases and the correct interpretation of the x-rays in the light of clinical signs is being, we believe, gradually attained. While these so-called scolioses do not belong at all in the same class as the structural curves of adolescence, yet their cause may lie in the same region as the numerical variations which Böhm found associated so frequently in the structural cases. Goldthwait has demonstrated the prevalence of these varying articular and transverse process shapes and explained their bearing on back strain, and Adams is finding that the vast majority of the cases of scoliosis under treatment by him in the Orthopædic Clinic of the Massachusetts General Hospital have some abnormality of shape or articulation, the significance of which is gradually being learned.)

FRACTURES AND DISLOCATIONS OF THE SPINE.

Malkwitz[45] reports nine cases from Hoeftmann's clinic of total dislocation of the cervical spine without symptoms of injury to the spinal cord. Clinical and x-ray observations as well as experiments on the cadaver show that a total dislocation of the cervical spine does not necessarily produce a lesion of the spinal cord. Frequently the posterior roots and the spinal ganglia are injured and cause lasting symptoms. The spinal cord in these cases may show an S-like curve. The author believes that the reason why an injury of the spinal cord does not always take place is to be seen in the marked

tilting of the posterior part of the displaced vertebra in anterior dislocations, and vice versa in posterior dislocations. In two of his cases a simultaneous fracture of the arch of the vertebra occurred also, which may be another reason for the absence of cord compression.

(Ed Note. Corner[46] and Mixter and Osgood[47] have reported series of cases of fracture and subluxation of the upper cervical vertebrae without immediate symptoms of cord compression, but the danger in these cases where there are no immediate symptoms is the gradual development of a myelitis from irritation and late bony proliferation. These late and sometimes fatal symptoms have ensued months and even years after the injury and indicate the necessity of exact diagnosis, exact replacement and freedom from irritation accomplished by fixation for a long period after the accident.

Lewandowsky[48] emphasizes the importance of a careful consideration of the clinical symptoms after a back injury in which x-ray picture may reveal nothing absolutely positive. He believes that compression fractures, especially of the lumbar vertebrae, are not uncommon and can only be surely diagnosed by clinical symptoms, but can be frequently confirmed by very careful x-ray examination. On the other hand Rhys[49] cites six cases of what in the x-ray plates appear to be definite fractures of the transverse processes, a distinct gap appearing between the "fragment" and the base. Three of these cases showed a displacement of the outer end up or down. Two cases showed thickened edges of the "line of fracture," suggesting a callous or a joint. These six cases he considers to be only pseudo fractures and to represent imperfect ossification or epiphyseal displacements due to the pull of an attached muscle. Only two of his cases had any history of injury and these injuries were slight. These epiphyses may not ossify until the twenty-fifth year and incomplete ossification may account for the gap.

(Ed. Note: Any large series of good x-rays of the lumbar spine is likely to show gaps of incomplete ossification of the transverse processes and occasionally of several of the transverse processes and on both sides. While we believe true fractures of the transverse process may and do occur, the importance of discriminating between these rare fractures and the commoner abnormalities of ossification is at once apparent in relation to workmen's compensation laws and possible operative treatment.)

MISCELLANEOUS.

Hawley[50] has invented an orthopaedic table which is most easy of operation and most skillfully devised. It meets the various requirements for the treatment of fractures and various orthopaedic conditions demanding fixation, traction, and the application of plaster to the trunk and lower limbs better than any table with which we are familiar.

Newton[51] has conducted an experimental investigation on concussions of the spinal cord. The spinal cord was exposed by laminectomy in the mid dorsal region in three monkeys, 8 dogs, and 39 cats. He has been impressed by the extreme sensitiveness of the cord to slight degrees of compression and concussion and by the considerable disturbance of function with very slight anatomical changes. As a result of his work he has come to believe that there are organic reasons for the symptoms of "railway" and "traumatic" spines, and that very slight effusions or hemorrhages from moderate trauma often cause marked disturbances.

There has been much discussion as to the most advantageous position in which to apply fixative treatment to the spine. Allison and O'Reilly[52] by means of x-rays taken in a special frame for the purpose of accurate comparison have studied the effect of various methods of traction and hyperextension in a case of old Pott's disease with considerable deformity and in the normal child. They conclude that vertical traction with hyperextension gives the best position of the vertebral bodies.

Goldthwait[53] believes that orthopaedic principles should be applied to the treatment of abdominal visceroptosis and chronic intestinal sepsis. It is evident that associated with these conditions are constantly found most extreme cases of faulty posture and frequently the chronic arthritides. He is convinced that by the remodelling of the body by means of positional bed treatment, apparatus, and exercises the faulty posture may be corrected, the ptosis improved, and what is more important, the general health of body and mind immensely changed for the better. Frequently the chronic joint symptoms disappear, and while congenital abnormalities may still condition to some extent the patients' complete return to robust health, these individuals may still be enabled to lead active and useful lives.

The importance of attacking these problems early is emphasized by Vorechelli[54] in a study of the etiology and therapy of dorsal curves. An observation of 906 pupils of elementary schools for girls and boys showed only 37% who were considered normal; over 27% who had varying degrees of what he calls flaccid dorsal curves or "respiratory dorsal curves" with asthenic thoraxes, and over 14% showed some degree of real scoliosis. It was of interest also that the flaccid dorsal curve is most frequent among the little children of the elementary classes, while the scoliotic deviations occur in the older classes, the inference being that the flaccid dorsal curve frequently changes into the scoliotic. Exercise in the open air he believes

to be the rational treatment and the benefit of this he has demonstrated.

Less has been written concerning the "congenital flat-foot" than concerning the congenital club-foot, and it is not rare to find neglected cases of the former condition. Legg[55] believes that a foot which by the third or fourth year has not developed a longitudinal arch, and whose scaphoid bone is not raised from the level of the sole, will gradually develop bony changes in the tarsus and remain flat permanently. He recommends the transplantation of the tibialis anticus to give a more correct pull. He reports ten cases with good results.

Kuelm[56] calls attention to the benefit attained in the case of a man of 68 suffering from intermittent claudication by the use of the faradic current applied while the legs were immersed in warm water. The case is interesting since the relief had lasted for six years at the time of reporting, and the pulse, imperceptible at first, became palpable again after twelve sittings.

(Ed. Note: The relief of this condition in our experience hs been most difficult and the condition is distressing. In two instances lasting relief has been obtained in our hands after the use of light electric vibration and with the report of Kuelm's case we should certainly attempt to stimulate the circulation by gentle methods of hyperaemia.

Drs. Dufour and Bertin-Mouret[57] report a case of Paget's disease in a woman eighty years old. The age of onset was unusual, beginning in her sixty-eighth year. The extreme pain in the extremities was sufficient to make her apply for admission to the hospital. After a positive Wassermann reaction three doses of neosalvarsan were cautiously given with intervals of twelve and thirty days. The pains disappeared and the case improved. The case is noteworthy on account of the treatment and improvement and also on account of the age at which the neosalvarsan was used.

M. Gangolphe[58] reports a case of pretabetic osteoarthropathy in a syphilitic fifty-seven years old, who had a partial absorption of the astragalus and bony proliferation around the lower ends of the tibia and fibula, following a fall. There were no medullary symptoms present, except impotence.

Mintz[59] has treated four cases of lesions of the tibial tubercle of the type of the so-called Osgood-Schlatter disease. He believes that the cause is not a partial avulsion of the tubercle, but that some unknown cause produces atypical bone formation. With the end of the growing period the disease stops. He operated upon two of his cases and the microscopical examination showed rarefaction, osteoclasis, and new formation of osteoid tissue and bone. He calls attention to the fact that similar lesions are found in other places as well, for example, at the epiphyses of the base of the fifth metatarsal bone and at the olecranon.

(Ed. Note: We admit that the exact cause of these lesions is not apparent, but it is a significant fact that they usually occur in active athletic adolescents or pre-adolescents, and only as far as we are aware at the points where powerful muscles are attached. We have a case under observation at present who presents these lesions at one tibial tubercle, the base of one fifth metatarsal, and at the apophysis of one os calcis. We are therefore inclined to believe that strong muscle pulls on appropriately formed growing bone centres, plus perhaps some not understood individual peculiarity in the structure of the epiphyses are the chief factors.)

Musgrave, Sison, and Crowell[60] have made x-ray and microscopical studies of twelve cases of bone lesions following smallpox. The long bones and their joints are most commonly affected and the lesions are always found in persons who have had the disease in early life, in none of their cases after 14 years of age. The diaphysis is shortened and the epiphyseal region distorted. The condition is evidently due to some change at the epiphyseal line which prevents the growth of the shaft. The contour of the shaft and its structure are unaltered. No microscopical changes were found.

Symmes and Wallace[61] have found pathologic changes in the thyroid glands in the cretinistic variety of chondrodystrophia foetalis and they recognize in these cases a type of chondrodystrophia in which the modifications in the soft tissues are comparable with those generally admitted to be due to defects of the thyroid gland.

(Ed. Note: Certain of the dwarf characteristics of the achondroplastic individual may be roughly compared to the peculiarities of the cretin. It seems most probable that there are some of these abnormal human variations that are deficient at the same time in many ways and we should expect dyspituitarism to be associated with disturbed secretion in other ductless glands. If we recognize achondroplasia as caused by a restriction of the activity of the hypophysis due to early ossification of the tribasilaris we may expect that in these cases various abnormalities may co-exist. Changes in the thyroid may be one of those concomitant abnormalities.)

Matts[62] has studied the changes in the bones of young dogs after excisions of the thymus gland. After complete excision there were distinctly progressive changes in the skeleton consisting of softening and bowing of the bones. This went hand in hand with a very marked weakness of the muscles and resulted in complete cachexia with impossibility of locomotion. Under the microscope a distinct similarity to rachitic changes was observed, evidenced by the

occurrence of limeless bone tissue of very large extent. This change was caused by resorption of calcified bone and extensive new formation of osteoid tissue. From this morphological similarity of the processes after thymus excision to the changes in human rickets, it is not conclusively proved that both processes are of the same nature, but the similarity is at least suggestive.

(Ed. Note: An interesting case in this connection has been observed by the editors which seems also possibly suggestive. An operation was performed for the correction of a disabling coxa vara in a case of marked adolescent rickets. A septic infection at first mild but uncontrolled by free drainage occurred, to which the boy succumbed. At autopsy a very large thymus gland and a status lymphaticus was found.

Reports of Societies.

NEW ENGLAND PEDIATRIC SOCIETY.

Twenty-eighth meeting held at the Boston Medical Library, December 12, 1913.

FRITZ B. TALBOT, M. D., SECRETARY.

DR. THEODORE W. ELY read a paper entitled

ALCOHOLIC CIRRHOSIS OF THE LIVER IN CHILDHOOD WITH REPORT OF TWO CASES.

Abstract: The paper contained a brief review of the literature on the subject with a resumé of the general symptomatology. Two probable cases in twin boys of four years, and the post-mortem findings in one of these cases were reported.

DISCUSSION.

DR. HOWARD T. KARSNER: Unfortunately, it was not possible to give Dr. Ely the description of histological material in the autopsy report. Grossly, the liver is not the "hob-nail" liver commonly seen in alcoholic cirrhosis and microscopically there is nothing in the nature of hyalin or other change to indicate a typical alcoholic form. To the contrary, the histological picture is that of cicatrization and attempted repair following an extensive acute destructive lesion similar if not identical with acute yellow atrophy. That alcohol can produce such a destructive change has not been demonstrated and therefore the etiological agent in this case must remain in doubt.

DR. ELY: I have nothing to add except to say that cirrhosis of the liver due to other cause was ruled out from the fact that the evidences of liver impairment were present before the attack of measles. Aside from this acute infection, I think all the more common causes of cirrhosis in childhood were ruled out by the history, physical findings and clinical tests.

DR. W. E. LADD read a paper on

THE TREATMENT OF TUBERCULAR CERVICAL ADENITIS IN CHILDREN.

Abstract: The various forms of treatment in vogue at the present time reviewed. He reported 83% of cures in a series of forty cases by thorough extirpation of all infected glands with the primary focus and recommended this form of treatment as it apparently yields 30 to 40% more cures than any other yet devised. Active tubercular lesions in the tonsil were found to be more common than had been previously reported.

DISCUSSION.

DR. CLEAVELAND FLOYD: I think something ought to be said on the other side of this subject. In each of the three series of cases which have been quoted, showing such a large percentage of cures, there has been one death following operation. Two of these deaths were due to acute general tuberculosis. In other words following the operation of tubercular cervical adenitis death does occur and it is not very uncommon that the local process becomes a general one. I know of several such results. No

one will deny that good hygiene is a part of any treatment of tuberculosis no matter where the disease is located.

The point made by Dr. Ladd in regard to removal of the tonsils is an excellent one. The tonsil is commonly the primary focus of the disease and should be removed in all cases. After this has been done however, the glands will take care of themselves and should be let alone.

The men in charge of surgical clinics speak of the poor results they have seen as the result of the use of tuberculin. The same thing is true of the work of the surgical clinic, in that the men using tuberculin are often called on to treat a case of tubercular adenitis after two or three operations have failed to give relief and the scars themselves have become infected. The time required to get good results with tuberculin has been urged as a point against it. In every case of localized tuberculosis prolonged observation is an excellent thing for the patient in order that his mode of living may be supervised. This far outweighs the value of the loss of time borne by the patients. If the tonsil, as the primary focus of tubercular adenitis is removed and such glands as have broken down are drained, then I believe that surgery has done all that is required. Palliative surgery with tuberculin and prolonged observation, will give more lasting results without complications, than can be obtained by surgery alone.

DR. H. I. BOWDITCH: I am glad the question of tubercular adenitis has been brought up because I think it is good to thrash it out. Some years ago, when tuberculin was first started here in Boston, I was interested in the tubercular glands of the neck at the Out Patient Clinic of the Children's Hospital, and I tried in a very small way the tuberculin injection, choosing children who had a sinus. As I remember it, they were very few in number, but they seemed to me to clear up very rapidly with the tuberculin treatment. I agree with Dr. Floyd and Dr. Ladd in having the tonsils out where they seem to be the cause of the infection, but I am not quite sure yet where surgical treatment comes in to the best advantage of the child. However, I think that the tuberculin treatment is of advantage. In other words, if you put me to the test, I should give tuberculin before I should do an extensive operation on the neck. There is another point which must be considered *i. e.*, that it is possible that some of these cases of cervical adenitis are not of tubercular origin.

DR. CHARLES G. MIXTER: The surgeon does not object to tuberculin as a medical procedure but what he believes in is that when tuberculin has been tried and the glands do not subside that the case should be considered a surgical one, and not wait for one abscess after another to appear. Then you can hope for a radical cure, for in this way you get rid of the glands.

DR. CLEAVELAND FLOYD: I was much interested in listening to Dr. Mixter's experience in having seen one abscess after another. It is rather an unusual thing with the use of tuberculin. Tuberculin is useful in the bilateral cases also, and in cases which have broken down it cleans up the sinus and we do not see a succession of abscesses. Some difficulty is experienced in a few of the cases, for it is not an uncommon thing for them to receive one or two doses of tuberculin and then disappear for two or three months, having in the meantime gone the round of the hospitals.

DR. J. S. STONE: There is one point upon which we are all agreed. The tonsils must be removed. I think if we do that, and do it early enough, the end results, no matter what other treatment is added, are going to be much better.

DR. LADD: I think Dr. Floyd has brought up a question of surgical accident which has always been a drawback to surgery. We all have to admit that we do occasionally lose cases through surgical accident but I do not think that the results with tuberculin are convincing enough for us to give up surgical measures in these cases. The question of abscesses not following one after another in his experience I think is rather unique. I have seen a good many cases treated with tuberculin, and I have been in a position where I have had to dress them for the medical men, and have had not a few dressings to do in some instances. With regard to the question of stirring up a general infection, I think this is a very good one but it is uncommon. The tuberculosis of the neck is, in a large percentage of cases, a local thing, and the number of cases in which there is involvement of the lung or of other parts of the body is comparatively small. There are some cases in which there are involvements of the bones or joints besides the glands, or glands in other parts of the body than the neck. The few cases that I have seen that had other parts of the body affected have usually been benefited by the dissection of the neck and the removal of the tonsils.

DR. J. J. THOMAS of Boston, read a paper on

OBSTETRICAL PARALYSIS, WITH ESPECIAL RELATION TO TREATMENT.

Abstract: In obstetrical paralysis we have an injury of peripheral nerves, in the plexus, and the paralysis and atrophy are never as intense as in cases of poliomyelitis, because of partial recovery. The treatment is surgical by resection of the injured nerves by transplantation of muscles. The most effective treatment in milder cases is that by educational exercises devised to train the child to use the weaker muscles and so develop them instead of substituting the action of the stronger muscles which produces awkward roundabout ways of achieving the purpose aimed at.

DISCUSSION.

DR. WALTER B. SWIFT: I should like to ask how Dr. Thomas would account for the recovery in these cases of obstetrical paralysis. Is it a regeneration of neurones or a resumption of function where fibers have been temporarily merely functionally involved, or is the recovery a muscle change?

DR. J. S. STONE: Anything which causes muscular relaxation, whether it be the etherization of the child through etherization of the mother or whether it be the relaxation of muscles from asphyxia or other cause plays a very important part in the etiology. Early support to the paralyzed muscles to prevent their being over-stretched is of extreme importance. While they are paralyzed they must be supported, because recovery is much better if they are supported. The lesion is mechanical. The problem would be purely surgical if the injury was a knife-cut. The difficulties of surgical interference are that in every case some of the fibres are torn, some of the fibres are stretched and some of the fibres are pressed on by the exudation into

the surrounding tissues. If we could only tell how extensive the tearing is then the problem would be more frequently a surgical one. There is a further difficulty that in many cases the injury is in a location which cannot be reached, that is, close to or even within the foramena. Personally I hope to see more and more progress along surgical lines. The problem is a mechanical one. The difficulties in surgical treatment are now very great.

DR. THOMAS, in closing: Of course training of muscles does not cure the condition in the nerve fibres. What I think is that stretched fibres recover in time by the natural regeneration when they have not been actually torn. This recovery is proved by the regaining of some power of voluntary contraction which is practically always seen to some extent. What a system of muscle training does is to teach the child to use these weak muscles, instead of substituting awkward movements to accomplish its object, by using the stronger muscles, and in this way we develop the weak muscles. Such a method, as I have said, to be successful, should begin early, before permanent changes in the affected muscles have taken place, and they require the treatment over quite a long time.

DR. PHILIP H. SYLVESTER read a paper on

SOME TRAGIC ASPECTS OF WHOOPING COUGH.*

DISCUSSION.

DR. CLEAVELAND FLOYD: I think the first case was one of considerable interest from a bacteriological standpoint, with the appearance of a large number of cells in the spinal fluid, then the appearance of staphylococci, the case going on to be a chronic one pointing towards recovery. It is quite an unusual thing to have staphylococcus meningitis, in the first place, and to have recovery in the second. I should like to ask Dr. Sylvester if he will give us a clear idea of what we ought to do in the prophylaxis and treatment of whooping cough.

DR. L. W. GILBERT: I think that something can be done regarding prophylaxis of whooping cough in the schools. The medical examiners who go to the different schools see a great many cases of children with cough without any definite whoop. One year when I was inspecting the schools in Brookline I made it a rule that a child who coughed for three or four days should be sent home, and the result was that instead of having a severe epidemic of whooping cough in a school which generally had one, I think there were something like twenty cases that year where they ordinarily had one hundred to one hundred thirty.

DR. SYLVESTER, in closing: In regard to prophylaxis, of course we all know that it is very difficult to tell at first whether a child is going to have whooping cough or not, but when we have a cold in a child with a cough, after exposure, we are justified in isolating that child to see how it will turn out. It seems to me that the regulations regarding whooping cough should be a great deal more stringent because, as statistics show, ten thousand or more children die annually with this disease in the United States. I think our Boards of Health should adopt more stringent measures regarding the control of this disease, and have the power to isolate all cases. As far as treatment is concerned, I suppose anything that helps is treatment. I do not know of any one thing which will give results in any one case. We have to try them all out, vaccines, bands and vaccination, and when a case is severe at all, I put most of my faith in sedatives to keep down the intensity of the paroxysms and to reduce their number.

* See page 406.

Book Reviews.

Die Störngen der Männlichen Geschlectsfunctionen und ihre Behandlung, VON DR. EMIL KANTOROWICZ. Berlin, Wiener: Urban and Schwarzenberg. 1913..

In this small handbook of 118 pages the author presents in concise and readable form under clear headings many facts regarding the sexual life, both in its normal and pathological aspects. Its practical value is increased by a discussion of the treatment of various sexual conditions. It is illustrated by eleven cuts, and in general is a useful book of its kind, brevity being not the least of its virtues.

A Manual of Venereal Diseases. Introduction by SIR ALFRED KEOGH, K.C.B.; History, Statistics, Invaliding, etc., BREVET COL. C. H. MELVILLE, R.A.M.C.; Clinical Pathology and Bacteriology, BREVET COL. SIR WILLIAM LEISHMAN, K.H.P., F.R.S., R.A.M.C.; Clinical Course and Treatment, MAJOR C. E. POLLOCK, R.A.M.C. Second edition, revised and largely rewritten, with new matter by L. W. HARRISON, R.A.M.C. Oxford Medical Publications. London: Henry Frowde, Hodder and Stoughton. 1913.

This is an admirable book, written by officers of the British Army Medical Service, on the practical problems of venereal disease. Considerable space is given the the history of syphilis, leading up to the discovery of its causative organism, and to a discussion of the Wassermann reaction, which followed. Several chapters are devoted to treatment by salvarsan and neosalvarsan, and a detailed description given of the various methods of administering mercury, with their relative advantages. Gonorrhea and the less important venereal disorders are given due space. In spite of the great number of books on the general subject of which this manual treats, we are not surprised that a second edition has been demanded. Although the modest statement was made in the preface to the first edition, that the book was "intended merely to act as a convenient manual, for the use primarily of the army medical officer, to assist him in his daily work in the prevention and treatment of venereal disease," we foresee for it a field of much wider usefulness. It will be of interest to sociologists that Sir Alfred Keogh, in his introduction, asserts with assurance that the legislative control of prostitution has certainly limited the spread of venereal disease in armies.

THE BOSTON
Medical and Surgical Journal

THURSDAY, MARCH 19, 1914.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States. $6.56 per year for all foreign countries belonging to the Postal Union.*

Papers for publication, and all other communications for the Editorial Department, should be sent to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston. All orders for reprints must be sent in writing to the Editor on or before the day of publication.

The Journal will furnish 100 reprints free, if requested in writing.

All letters containing business communications, or referring to the publication, subscription or advertising department of the Journal, should be addressed to the undersigned

Remittances should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

THE COOLIDGE TUBE.

IN the issue of the JOURNAL for Jan. 8, 1914, (Vol. clxx, p. 64), we made preliminary editorial comment on the new form of Roentgen tube invented by Dr. William David Coolidge, of New York, and first demonstrated by him before a meeting of physicians, physicists, and radiographers on Dec. 27, 1913.

In another column of the present issue of the JOURNAL, we publish an article by Dr. Van Allen, of Springfield, describing in more technical detail the Coolidge tube and its scientific and clinical advantages. The early anticipations of the great value of this instrument seem to be fully realized in practise, and its employment should mark the opening of a new period in Roentgen work.

To the roentgenologists who have worked with the Roentgen tube from its earliest form up to the present wonderfully developed transformer tube with its tungsten target, the Coolidge tube is a revelation far beyond what was ever hoped for. To have at one's command an instrument which makes it possible to give absolutely accurate exposures for roentgenographic work, roentgenoscopic observations, and also to be able to give a positively accurate dose when used as a therapeutic agent, reduces roentgenology almost to an exact science.

When Dr. Coolidge's invention is used in connection with a transformer which will give practically an unfluctuating, non-impulsive, unidirectional current, with which it is possible to use a volt meter in the tube circuit giving the absolute penetration of the tube indicated by kilovolts (thus eliminating the other somewhat inaccurate methods of penetration), then conditions of perfect accuracy are realized.

We already owe much to Dr. Coolidge for his development of the tungsten anodes, used in the present transformer tubes. His latest development leaves nothing to be desired as far as the Roentgen tube is concerned. With the Coolidge tubes, the operator can now get not only homogenetic Roentgen rays, but complete accuracy of dosage. This is of the utmost importance in all branches of this field, but particularly in roentgenotherapy. In this branch of the work, much more can now be accomplished than has ever before been thought possible.

In regard to the dangers from the use of the Coolidge tube, there seems no reason to believe that they are greater than from the previous type when used by those who appreciate the fact that every Roentgen tube is a source of danger when carelessly or ignorantly operated. The amount of energy that can be obtained from this tube is almost unlimited, but is absolutely under control. The penetrating power is still dependent upon the voltage impressed on the terminal of the tube, as in the older types. But the fact that its operation is no longer dependent on the presence of vapor in the tube, that simply by heating the cathode by means of a low voltage current, the tube can be operated at any desired penetration (such penetration being dependent upon the voltage delivered to the terminals of the tube and the amount of current being dependent upon the degree of heat applied to the cathode from the low voltage current), puts into the hand of the expert an instrument of precision in which there is no danger, providing he realizes its limitations.

For a more complete technical description of the tube and its methods of use, our readers are referred to the original article by Dr. Coolidge in the January (1914) number of the *American Journal of Roentgenology.*

MEDICAL LEGISLATION. REGISTRATION OF VITAL STATISTICS.

IN the issue of the JOURNAL for Feb. 26 (Vol. clxx, p. 325), we commented editorially on the proposed bill (House No. 1348) to amend the laws of this state in relation to vital statistics.

The essential provisions of this bill are embodied in three sections, as follows:—

"Section 1. The State Board of Health shall have charge of the compilation and tabulation of births, marriages, deaths, divorce returns and medical examiner returns, shall prepare for the Secretary of State the official report on these subjects to the General Court, including therein tables and analyses of morbidity returns, and shall from time to time recommend any additional legislation that may be necessary in relation to such statistics.

Section 2. This statistical work shall be under the management of a competent physician who shall be known as the State Registrar of Vital Statistics. He shall be appointed by the Governor with the advice and consent of the Council upon nomination by the State Board of Health.

"Section 3. All copies of births, marriages, deaths, divorce returns and returns from the medical examiners, called for by law shall be sent by city clerks and other officials to the State Board of Health. These copies and returns shall be used for statistical purposes by the State Registrar of Vital Statistics and then transmitted to the Secretary of the Commonwealth for permanent custody."

At present the death certificates are analyzed, tabulated and published by the Secretary of State. The medical department of health of the state, *i.e.* the State Board of Health, has nothing whatever to do with them. Under these circumstances it is not to be wondered that the statistics do not command the respect that they did when supervised by the secretary of the State Board of Health, as they were for half a century previous to 1890. Massachusetts was the first state in the country to have vital statistics, about 1843, and the death returns then ranked first in accuracy and efficiency. It is the restoration of these conditions which is intended by the present measure quoted above.

A hearing in favor of the proposed bill was held on March 5 before the committee on public health, and at this hearing the bill was advocated by various medical organizations.

The proposed legislation on vital statistics has been approved by The Massachusetts Medical Society—through its committee on state and national legislation—by the American Statistical Association and by the Massachusetts Association of Boards of Health.

The resolutions unanimously approved by the latter association are given below:—

"Whereas, One of the most important functions of boards of health is the prompt return of reliable vital statistics, and

"Whereas, the chief factors of vital statistics, the births and deaths, are medical matters and hence necessarily in charge of physicians, and

"Whereas, By reason of the character of the data involved, their supervision and tabulation can be much better done by a physician, who has been properly trained and educated for this work, and

"Whereas, The vital statistics of Massachusetts are in charge of the Secretary of State, instead of the medical department of the State, now, be it

"Resolved, By the Massachusetts Association of Boards of Health, in annual meeting assembled that it would be for the distinct advantage of the public welfare to have the vital statistics placed in charge of the State Board of Health for their proper arrangement and tabulation previous to their being given in charge of the Secretary of State for permanent custody. By this means the vital statistics would remain in the hands of the medical profession, where they naturally belong, until they have been put in proper shape for permanent record.

"Resolved, That appreciating the importance of the desired change and of the efforts now being made to bring it about, this Association most earnestly approves of House Bill, No. 1348, which simply directs that the vital statistics of this state on their way to the office of the secretary of state shall pass through the office of the State Board of Health for the purpose of permanent arrangement and tabulation."

THE REPORTING OF INDUSTRIAL DISEASES.

AMONG the acts of the Massachusetts General Court of 1913 was one (Section 6 of Chapter 813) which provided as follows:—

"The joint board (of labor and industries, and industrial accidents) may require every physician treating a patient whom he believes to be suffering from any ailment or disease contracted as a result of the nature, circumstances or conditions of the patient's employment to report such information relating thereto as it may require, within such time as it may fix, to the state board of labor and industries, and may issue a list of such diseases which shall be regularly reported upon by physicians and may add to or change such list at any time."

Under the provisions of this section, the board passed the following regulation:—

"Under authority of Section 6 of Chapter 813 of the Acts of 1913 the Joint State Board of Labor and Industries and Industrial Accidents hereby requires that every physician treating a patient whom he believes to be suffering from

poisoning from lead, brass, phosphorus, arsenic or mercury or their compounds, or wood alcohol, or from anthrax, or from compressed air illness, to report within 48 hours to the State Board of Labor and Industries, the information relating thereto called for by the reporting blanks issued by the said Board. Every such physician is hereby requested to make reports on the said blanks to the State Board of Labor and Industries of any patient whom he treats that is suffering from any other ailment or disease which the physician believes to have been contracted as a result of the nature, circumstances or conditions of the patient's employment."

This regulation became effective on March 1, and appropriate blanks for making reports have been distributed by the board to physicians throughout the state. The attention of all is called to this new piece of medical legislation and to their duty of compliance therewith.

MEDICAL NOTES.

London Death-Rates in January.—Statistics recently published show that the total death-rate of London in January was 18.4 per 1000 inhabitants living. Among the several districts and boroughs, the highest rate was 23.4 in Finsbury, a crowded central slum, and the lowest was 12.3, in Lewisham, an open southern suburb.

Xiphopagotomy.—In the issues of the Journal for Jan. 8 and Feb. 12 we commented on the recent birth of a pair of xiphopagi in France. Report from Paris states that they were surgically severed on March 4, and are both doing well. They were born on Nov. 28, 1913, and at that time weighed 10 pounds. Later report states that one of the infants has died.

Bubonic Plague in Havana.—Recent report from Havana states that a case of bubonic plague was discovered in that city on March 5, and a second case on March 10. The patients were isolated, and every precaution taken to prevent further spread of the infection. The first patient has already died, but no further cases have as yet been reported.

Injunction Against Iowa Sterilization Law.—Report from Council Bluffs, Iowa, states that on March 11 the United States district court granted a temporary writ of injunction against the enforcement of the Iowa sterilization law in a case filed at Keokuk.

Jordan Memorial Sanatorium.—The recently published first annual report of the Jordan Memorial Sanatorium at River Glade, N. B., records the work of that institution for the year ended Oct. 31, 1913. During this period 36 tuberculous patients were under treatment. The institution was created by legislative act in 1911, and the site and buildings were given by Mrs. James C. Jordan, of San Francisco. It is situated in Westmoreland County, seventy miles from St. John and twenty miles from Moncton. The first patient was admitted on March 17, 1913. Only cases in the early stages of phthisis are considered suitable for admission.

Typhoid Fever Near Montreal.—Report from Montreal on March 3 states that typhoid fever was then epidemic along the valley of the Richelieu river. A total of 400 cases has been reported. In the little town of St. John, 200 cases and 4 deaths have occurred. The infection has been traced to a polluted water-supply.

Investigation of Chinese Sanitation.—Report from Chicago on March 5 states that Dr. Harry Pratt Judson, president of the University of Chicago, has been appointed chairman of a commission of the Rockefeller Foundation to investigate medical and sanitary conditions in China. The commission will sail from New York on March 21. It will visit Paris, Berlin, St. Petersburg and Moscow on the way, and is due to reach Pekin on April 18.

Scarlet Fever in New Jersey.—Report from Florence, N. J., on Mar. 10 states that scarlet fever is epidemic in that town of 2000 inhabitants. There have been 35 cases since Dec. 1, 1913; there have been 11 deaths since Feb. 27; and 23 cases are now under observation. The local churches have been closed.

BOSTON AND NEW ENGLAND.

A Case of Smallpox in Dorchester.—A case of smallpox was recently discovered at Dorchester, Mass. The patient was removed to Galloupe's Island, and all ascertainable contacts were vaccinated.

TONSILLITIS IN WAKEFIELD.—The epidemic of tonsillitis in Wakefield and Stoneham, Mass., to which we referred in last week's issue of the JOURNAL, is reported as at an end. There was a total of about 400 cases.

MEASLES AT EXETER.—Report from Exeter, N. H., on March 6, states that measles was then epidemic among students in the local Phillips Academy. Twenty-eight cases of the disease had been reported on that date.

FIRE AT MILLET SANATORIUM.—Report from East Bridgewater, Mass., states that on March 8, five of the nine one-room houses of the Millet Tuberculosis Sanatorium were destroyed by fire, with an estimated damage of $2000. The patients were all removed to the main building.

REPORT OF THE BUTLER HOSPITAL.—The recently published seventieth annual report of the Butler Hospital of Providence, R. I., records the work of that institution for the calendar year 1913. During this period 249 patients were under treatment, over 40% of whom entered on voluntary application. A new operating room and dispensary have been established, and the new Potter Home for Nurses has proved useful and beneficial. On June 13, 19 nurses were graduated from the training-school.

BOSTON ASSOCIATION FOR THE RELIEF AND CONTROL OF TUBERCULOSIS.—The recently published tenth annual report of the Boston Association for the Relief and Control of Tuberculosis records the activities of that organization for the year ended Oct. 31, 1913. Of the eight legislative measures advocated by the Association during this period, six were enacted into law. Lectures and exhibits have been held, 171,000 pieces of literature distributed and 1,353,969 red cross seals sold. A domestic science visitor has been employed and follow-up work maintained. The Prendergast Camp has continued its work, and during the year was used by 61 patients.

THREE CENTENARIANS.—Mrs. Columbia Parris, of Paris, Me., who is said to have been born in March, 1814, celebrated recently her supposed centennial anniversary.

Mrs. Patrick Bowe, who died recently in Woburn, Mass., is said to have been born at Dublin, Ireland, in 1810. She migrated to the United States in 1844. Her husband died in 1912, at the alleged age of 101.

Mrs. Catherine O'Neill, who died recently at Hartford, Conn., is said to have been born in 1808. She had been a widow since 1854, but always enjoyed excellent health. She is survived by an aged son.

HOSPITAL BEQUEST.—The will of the late Annie Louise Cummings, of Portland, Me., which was filed on March 5, contains a bequest of $5000 to the Maine General Hospital.

NEW YORK.

BETH ISRAEL HOSPITAL ASSOCIATION.—The annual meeting of the Beth Israel Hospital Association was held on Feb. 26, when it was reported that 46,959 cases were treated at the hospital during the year. The total expenditures were $126,522 and the receipts, $114,171, the deficit of $12,351 being made up by the board of directors. The president announced that plans had been made for the construction of a new hospital on a site a little north of the present building (on the lower east side), which is to be 14 stories in height, with provision for 500 beds. The estimated cost is $1,000,000, and of this amount nearly $300,000 has already been subscribed.

TOMBS CITY PRISON.—Many abuses having been brought to light in an investigation of conditions at the Tombs city prison, Deputy Commissioner Lewis of the Department of Correction has recommended a number of important changes in the administration of the institution. Among his recommendations is that steps be taken to establish hospital wards on the top floor of the main building, which will permit the segregation in separate wards of those suffering from tuberculosis, venereal diseases, or the use of norcotic drugs, and which will secure to all inmates decent medical service, which is now made impossible because of the lack of facilities. Another of the recommendations is that a single story building should be erected in the yard space, where visitors may see inmates without congesting the main prison, as at present, and without coming in personal contact with the inmates. This will obviate the present dangerous possibility of escapes through substitution, and also obviate all searches of visitors, which are necessarily more or less obnoxious to them. The commissioner is convinced that drugs will

be smuggled into the prison as long as visitors can come in contact with inmates, and as long as food and beverages may be purchased outside and brought in.

The Milk Situation.—The New York Milk Committee has sent to Governor Glynn a protest against the personnel of the State Milk Commission recently appointed by him, asserting that in the commission, as it now stands, seven of its eleven members really represent the interests, not of the producer or of the consumer, but of the reactionary group of milk dealers and ice cream manufacturers who resent increasing demands of the public and such organizations as the New York Milk Committee for more rigid regulations to safeguard the consumer against impure and disease-laden milk With the exception of Health Commissioner Biggs and Nathan Straus, no member of the commission, it is stated, is qualified to represent in a disinterested way the best interests of the state from a public health standpoint. The New York Milk Committee has advocated uniform state regulations requiring the pasteurization of all milk except that which is certified and the grading of milk according to bacterial standards and methods of production. It may be recalled that, in order to secure pure milk at a reasonable price for use at the infant milk stations in New York City, the committee organized an experimental company, which for two years conducted a plant at Homer, N. Y., and demonstrated that milk equal in quality to regularly certified milk could be produced and sold at a fair profit for 9 cents a quart.

Registration of Nurses.—A hearing was recently held in Albany upon the two bills, in the senate and assembly respectively, known as the Seeley and Hoff bills, which are identical in their provisions and have the title, "An act to amend the public health law, in relation to the practice of nursing." They are in every respect similar to bills which were killed in the last legislature, having for their object the creation of a high-priced nursing monopoly, for the benefit of a few at the expense of the many. They would debar, under heavy penalties, all persons except "registered nurses" from calling themselves nurses, and are strongly opposed to the public interest, since no provision whatever is made for nurses for persons of moderate means, who comprise over 90% of the population; while instruction for low-priced nurses, which for nearly ten years past has been provided by an admirable and successful institution for the purpose at Albany, is forbidden under penalty of the law. At the hearing, among those who opposed the bills were representatives of no less than thirty-eight large hospitals in New York City, including such institutions as the Roosevelt and St. Luke's Hospitals, and from Albany the superintendent of the large City Hospital.

2. Ware endeavors to refute the claims made for phenolsulphonephthalein as a functional renal test. He says that the efficiency claimed for the drug because of its complete rapid elimination and its reappearance in an unaltered form cannot bespeak any elaboration in the sense of work done on the part of the kidney, for efficiency means the ratio of useful work to energy expended. The phenolsulphonephthalein test is an acidometric test, but the degree of acidity and kidney function are not necessarily parallel. The information obtained by this test is not precise. [L. D. C.]

17. HANSON, H. B. *Fuchsin Ointment in Tinea Sycosis.*

1. Pearce's paper is a very carefully prepared answer to the popular cry of "Human Vivisection." He shows how utterly unfounded and blind are most of the press or antivivisection journal statements. The paper is one that the laity should have recourse to in order to straighten out their misdirected ideas on this important subject.

2. Patterson's paper on the economic loss due to venereal disease is extremely convincing and should form a base for further efforts towards its control.

6. Pierson finds marked similarity between distemper in dogs and poliomyelitis in children, and writes a very suggestive paper. The subject seems worthy of further careful investigation.

10. Breitstein believes that a Cesareanized woman who gives a history of an infection with a purulent vaginal discharge in the puerperium is a good candidate for rupture of the uterus in one of her subsequent pregnancies. Rupture of a Cesarean scar generally takes place in a scar resulting from improper wound healing because of infection. [E. H. R.]

3. Penfold, W. J. *A Method of Producing Rapid and Fatal Intoxication with Bacterial Products.*
4. Mamourian, M. *The Radical Cure of Procidentia Uteri in Elderly Women.*

1. In an interesting article, but one which hardly lends itself to review, Ballantyne discusses pregnancy from various points of view. He speaks of the three theories in regard to it: First, that the embryo is a parasite living on the mother and making certain definite demands of the maternal organism; second, the pathological concept that pregnancy is a nine-months' disease from which the mother is suffering; and third, the view of those who regard pregnancy as a harmonious symbiosis, that the child is a part of the mother and that there is a certain amount of give and take on each side. He discusses the maternal response to pregnancy; that pregnancy is physiology at high pressure. He considers pregnancy and life insurance, the biological test for pregnancy, the etiology of the various maladies of pregnancy, its place in the medical curriculum, pre-maternity wards and ante-natal pathology. He briefly takes up pregnancy and its relation to legislation, eugenic feminism and politics.

2. Routh discusses the causes of ante-natal disease and death. Among the paternal causes he mentions syphilis and tuberculosis; among the maternal causes he includes: (*a*) pathological, such as malnutrition, acute and chronic diseases, tropical diseases and toxemias, (*b*) mechanical causes, and (*c*) miscellaneous causes, such as hemorrhage, etc. Among the fetal causes he includes: (*a*) developmental, (*b*) pathological, (*c*) mechanical. To meet and relieve these causes he discusses remedies under three heads: (1) philanthropic, (2) legislative, and (3) medical. He dwells at length on these headings. The article is of great interest and value. [J. B. H.]

1. To be reviewed in the next number.

3. Schottmüller recognizes that jaundice is a not infrequent complication of pregnancy. It may be of catarrhal nature, or due to pressure on the bile passages by the enlarging uterus or may be infectious or hemolytic. In extra-uterine pregnancy with bleeding into the peritoneal cavity, there occurs another kind of jaundice which is not hepatogenic. This is due to the absorption of blood elements from the peritoneum. It is recognized by spectroscopic examination of the blood, which shows the presence of hematin. Schottmüller therefore believes that the presence of hematin in blood is a valuable clinical sign of extra-uterine pregnancy and that jaundice from this cause is an important clinical symptom.

8. Mayer has cultured the stools from 5719 soldiers. In only three cases were pathogenic bacteria found. He concludes that healthy individuals in healthy communities are rarely the carriers of infection. To prevent diseases acquired through the intestinal canal, he advises the avoidance of foods which may contain germs, and insists on clean streets, drinking water, clean houses and clean hands as the best kinds of general prophylactic measures. 6. Schneider has made blood counts in 30 cases of whooping cough occurring in children of different ages. As a rule, up to the third week of the disease there is a leucocytosis of at least 27,000, becoming as high as 86,000 in complicated cases. During the first four weeks a relative lymphocytosis is found, varying between 58-63% of the white cells, while large mononuclear cells and transitional cells are only slightly increased. This blood picture is characteristic for whooping cough. The degree of leucocytosis, however, affords no prognostic information.

11. Döderlein and V. Seuffert have treated 180 cases of malignant disease with mesothorium. In this paper they give a careful analysis of their methods and results. They believe that mesothorium is a

good therapeutic agent in certain kinds of disease, and feel that further progress in its use can be made only by more confirmation by others. [R. F.]

3. The author advances the theory that leukemia may be a secondary or tertiary manifestation of some antecedent disease, just as there are secondary and tertiary lesions of syphilis. He has no data or proofs, but merely suggests that all cases of leukemia be subjected to an exhaustive questioning on the past history, to see if any one pathological process appears consistently in these histories. He thinks that possibly valuable light may be thrown on the subject in this way.

4. Klose in this article takes up the importance which the thymus has come to assume in Basedow's disease, and the definitely recognized deaths which have occurred after operation as a result of either pressure or intoxication from a pathological thymus. He classes all cases of Basedow's disease into: (1) those showing primary involvement of the thyroid with slight or no involvement of the thymus, (2) those in which the two glands are similarly diseased, and (3) the rare cases where the thymus alone is accountable for the symptoms. Correct diagnosis in the last two groups is difficult even with the best hospital facilities—indeed it is often impossible. During the last two years at the Frankfort clinic they have removed the thymus wholly or in part in every case in which it was suspected of being involved in the process, with startling results. Up to 1911 there were 130 operations with 8 "thymus deaths"—in 1912 and 1913 there were 200 operations with no deaths. The removal of the thymus was in addition to the thyroidectomy. The operation was always done under local anesthesia if possible, and the thymus was removed by enucleation within its capsule. [R. H. M.]

3. Werkowski has studied this subject exhaustively; he reports several cases, and concludes: (1) that radium and mesothorium have a marked destructive influence on carcinomatous tissue, different from any other substance yet discovered; (2) that growths which are resistant to the Roentgen ray are often influenced by radium; (3) that the most important factors for success are the amount of the radio-active substance used, the filtration, and the proper regulation of the distance between the radium and the carcinoma.

5. The author reports 74 cases of carcinoma of the skin treated with mesothorium, with the following results:—

Thirty-three cases were clinically cured, showing, at the time of the report, clean scars at the site of the disease, with no evidence of malignant infiltration.

Three cases which had recurrences after treatment were subjected again to the mesothorium and were clinically cured.

Four cases were refractory and showed no improvement.

Twenty cases were still undergoing treatment and no definite report could be given.

Fourteen cases were lost sight of, and were not available for this report.

The results with deep-seated inoperable tumors were much less satisfactory. [R. H. M.]

2. Wossidlo made numerous experiments upon dogs for the sake of determining the amount of damage done to kidneys by the injection of collargol, as it is used in pyelography. He found that when collargol is injected into the normal, uninjured pelvis in amounts no greater than the capacity of the pelvis, none of the silver enters the kidney proper or the tissues about the pelvis. If the amount injected is in-

creased beyond the normal capacity of the pelvis, collargol escapes into the peripelvic tissues and spreads over the surface of the kidney beneath the capsule. If the lining of the pelvis is injured, as by the ureteral catheter, the collargol, if under pressure, escapes into the interstitial tissues beside the blood-vessels and between the tubules, and by way of these interstitial spaces may pass into the spaces of Bowman's capsule in the glomeruli. In hydronephrosis, the collargol passes into the collecting tubules much more than in the normal kidney. Infarcted kidneys take up the collargol when it is under pressure, but only in their healthy portions. The infarcted area remains free. From these experiments Wossidlo advises never distending the pelvis beyond its capacity; in hydronephrosis, put in only as much collargol as there is residual urine. If there is primary bleeding, as is often found with stone, tuberculosis or tumor, do not use collargol; if there is secondary bleeding due to injury from catheterization, be careful to underdistend rather than overdistend the pelvis. He concludes by saying that his experiments were not very satisfactory, but he hopes to present a more complete study in the near future. [G. C. S.]

7. BUJWID, O. *Employment of Virus Regenerated by Transmission in the Treatment of Rabies.*

1. In this article Metchinkoff reports the results of further experiments with the products of intestinal putrefaction. In former work his associates have claimed that indol and paracresol have produced sclerotic lesions in organs and vessels of animals. In this report he shows that the potassium sulphate of these bodies has a toxic action for animals and then he claims that in addition to producing sclerotic lesions these substances are toxic even after combination with body salts. He simply states that therefore another proof is added to the claim that bacterial action against the organisms which produce these substances is justifiable.

6. In a medium which Besredka and Jupille prepared during their studies on anaphylaxis they have had excellent results in growing practically all the organisms, which they have tried out. They have grown better than on the usual media employed for such purposes the pneumococcus, meningococcus, streptococcus, gonococcus, typhoid bacillus, paratyphoid, colon, melitensis, cholera vibrios, diphtheria bacillus, cholera in chicken bacillus, tetanus bacillus and bacillus prodigiosus. The organisms grow more rapidly and preserve their vitality longer. The medium is made as follows:

Egg white (diluted 1:10) .....4 parts
Egg yolk (diluted 1:10) .....1 part
Ordinary bouillon .....5 parts

2. In reviewing her work, and that of other investigators during the past ten years, Dr. Luzzani reports as follows in regard to her feelings concerning the value of making a diagnosis of rabies by demonstration of the specific parasite, namely the negri bodies:—

The demonstration of the specific parasite discovered by Dr. A. Negri furnishes the surest and quickest method for making a diagnosis of rabies, not only in the dog, but in all other animals susceptible to the disease. The hippocampus major is that part of the brain in which the parasites are most numerous. At this point the forms are more developed and appear earlier in the disease. However, if this part of the brain cannot be obtained, a diagnosis is possible from examination of the other parts of the central nervous system. The author favors the examination in the fresh state after breaking up the tissue. If this fails, the staining method of Mann upon Zenhu fixed material is the best. A positive finding of negri bodies settles the diagnosis, but if the histological study is negative, an experimental inoculation is advisable.

BULLETTINO DELLE SCIENZE MEDICHE.

MAY, 1913.

1. *LONGO, C. *The Action of Sodium Chloride on Normal and Pathologic Kidneys.* (*Conclusion.*)

1. In this exhaustive continued article, Longo reports clinical observations on two cases of hemorrhagic, one of chronic interstitial, and one of chronic parenchymatous nephritis, and laboratory results from four series of animal experiments with uranium nephritis, from which he reaches the following conclusions relative to the importance of sodium chloride in the dietetic regimen of nephritics.

(*a*) The moderate and protracted use of sodium chloride has an irritating action on normal kidneys.

(*b*) This action is greater in nephritic kidneys.

(*c*) A systematic, properly watched, and regularly applied dechloridized regimen for nephritics is the most rational and presents no inconveniences or special contra-indications.

(*d*) The ordinary regimen, containing the ordinary quantity of supplementary salt cannot be tolerated by any nephritic, acute or chronic.

(*e*) In chronic nephritides with chloremic syndromes the sodium chloride exchange is notably altered.

(*f*) There is a parallelism between retention of chlorides and appearance of edema in nephritics.

(*g*) The milk regimen cannot be given to all nephritics, with impunity.

(*h*) Demineralization of food in the uranium nephritides has notable advantages.

(*i*) Clinically and experimentally, the subtraction of chlorides from the food, even if prolonged, does not cause in nephritics any disturbance of the nitrogen exchange.

(*j*) Only on the guide of the balance of chlorides, respecting the special eliminating function of the kidneys for these salts, can be fixed the opportune grade of the hypochloridized regimen.

Miscellany.

NOTICES

THE CUTTER LECTURES ON PREVENTIVE MEDICINE AND HYGIENE. I. By Charles V. Chapin, M.D., Superintendent of Health, Providence, R. I., on "Municipal Sanitation."

Friday, March 20, "Science and Sanitation."

Friday, March 27, "Efficiency of Public Health Measures."

Thursday, April 2, "Organization of the Health Department."

Thursday, April 9, "Research and Publicity."

Thursday, April 16, "Nuisance Problems."

Thursday, April 30, "Contagious Disease Problems."

II. By Cressy L. Wilbur, M.D., Chief Statistician, Bureau of the Census, Department of Commerce on "Vital Statistics in Massachusetts and the United States," Wednesday, March 25, and Thursday, March 26.

Harvard Medical School, Amphitheatre Building A, at 5 p. m.

These lectures are given annually under the terms of a bequest from John Clarence Cutter, whose will provided that the lectures so given should be styled the Cutter Lectures on Preventive Medicine, and that they should be delivered in Boston, and be free to the medical profession and the press.

The members of all classes in the Medical School, the medical profession, the press, and others interested are cordially invited to attend.

MASSACHUSETTS GENERAL HOSPITAL.—A surgical meeting open to the medical profession will be held at 8.15 p. m., on March 27, in the lower amphitheatre of the Out-patient Department. Entrance on either Blossom or Fruit Streets.

Dr. W. J. Mixter will present a "Report on Cranial Surgery at the Hospital since 1901."

Dr. E. P. Richardson will present a "Report on Operation for Hemorrhoids at the Hospital since 1901."

Dr. T. W. Harmer will present a paper on "Mixed Toxins (Coley) in Certain Cases of Sarcoma."

UNITED STATES CIVIL-SERVICE EXAMINATION.

MEDICAL INTERNE,

GOVERNMENT HOSPITAL FOR THE INSANE.

April 8 1914.

The United States Civil Service Commission announces that senior students of reputable medical colleges will be admitted to the open competitive examination for medical interne in the Government Hospital for the Insane, to be held on April 8, 1914, upon filing applications showing them to be otherwise eligible; but in the event they attain an eligible average in the examination their names will not be entered upon the eligible register until they have furnished proof of actual graduation from such colleges.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—A meeting of the Society will be held in Sprague Hall, Medical Library Building, on Monday, March 23, 1914, at 8.15 p. m.

Addresses:

"Horse Asthma in its Relation to the Administration of Diphtheria Antitoxin," Dr. Joseph L. Goodale.

"Remarks on the Work and Theories of Dr. S. Weir Mitchell," Dr. James J. Putnam.

After the addresses there will be an informal discussion of the activities and future of the Society, in order to obtain an expression of opinion as to its policy. A full attendance of members is therefore earnestly desired.

E. W. TAYLOR, M.D., *President.*
ROBERT M. GREEN, M.D., *Secretary.*

AMERICAN SOCIETY FOR THE CONTROL OF CANCER.—The American Society for the Control of Cancer has made arrangements for a special meeting on cancer to the held at the New York Academy of Medicine, 17 West 43d Street, on Friday evening, April 10, 1914, at 8.30 p. m. This date has been selected in order that physicians and surgeons attending the Congress of the American Surgical Association may conveniently be present. The public is also invited.

Dr. William J. Mayo, of Rochester, Minnesota, President of the American Surgical Association and Frederick L. Hoffman, LL.D., statistician of the Prudential Insurance Company will discuss the problem of cancer and its control. Dr. Francis Carter Wood, Director of the George Crocker Research Laboratory will describe the investigation of cancer which has been undertaken there under the auspices of Columbia University. Dr. J. Collins Warren of Boston, Professor Emeritus of Harvard University, and President of the Harvard Cancer Commission, will give an account of the estblishment of that commission and the research work which it is directing at the Collis P. Huntington Memorial Hospital, and the Harvard Medical School.

THE BOSTON SOCIETY OF MEDICAL SCIENCES.—The next meeting will be held on Tuesday evening, March 24, 1914, in the Out-patient amphitheatre of the Massasetts General Hospital, at 8.15 o'clock.

The meeting will be conducted by the Staff of the Massachusetts General Hospital.

Papers will be presented as follows:

Dr. Otto Folin and Dr. W. Denis: "Some New Chemical Methods for the Clinical Examination of Urine." (15 minutes.)

Dr. J. H. Means: "Study of Blood Acidity by the Method of Barcroft." (15 minutes.)

Dr. J. H. Pratt: "State of the Vaso-motor Mechanism in Diphtheria Intoxication." (10 minutes.)

Dr. L. H. Newburgh: "State of the Vaso-motor Mechanism in Pneumonia." (15 minutes.)

THOMAS ORDWAY, *Secretary and Treasurer,*
Harvard Medical School.

RECENT DEATHS.

DR. EMILY H. SAWYER, who died recently in West Somerville, Mass., was born at Girard, Pa. She studied at the Boston College of Physicians and Surgeons, and for thirty years had practised her profession in Somerville. She was a widow.

DR. FRANCIS M. BURKE, of Brooklyn, N. Y., a graduate of the medical department of New York University in 1890, died on March 3, at the age of 53.

DR. HUBERT NICHOLS, of Brooklyn, N. Y., a graduate of Bellevue Hospital Medical College in 1891, died on March 9, at the age of 49.

DR. WILLIAM C. MONROE, who died on March 11, at Woonsocket, R. I., was born in 1849. He received the degree of M.D. in 1876 from Bellevue Medical College. He was chief of staff and chairman of the medical board of the Woonsocket Hospital, a member of the Rhode Island Medical Society and first president of the Woonsocket District Medical Association.

DR. JOHN LAING LEAL, who died on March 14 in Paterson, N. J., was born in Andes, N.Y., in 1858. He received the degree of A.B. in 1880 from Princeton, and in 1884 that of M.D. from the College of Physicians and Surgeons of New York. In 1888 he settled in the practise of his profession at Paterson, where he became an expert on sanitation, and was for many years president of the local board of health. He was consulting surgeon for the Paterson General Hospital and examiner in the School of Hygiene of Rutgers College, and president of the New Jersey State Sanitary Association.

Original Articles.

THE TREATMENT OF SYPHILITIC DISEASES OF THE CENTRAL NERVOUS SYSTEM BY INTRAVENOUS INJECTIONS OF SALVARSAN.*

BY LESLEY H. SPOONER, M.D., BOSTON.

[From the Department of Neurology of the Massachusetts General Hospital.]

This work, started in August, 1911, has been conducted exclusively in the ambulatory neurological clinic of the Massachusetts Genral Hospital. It has been impossible to utilize the wards owing to the limited accommodation of this department, except for the recovery from lumbar punctures, which were performed as a control to treatment. This rendered the investigation more difficult; but the results fully justify this means of treatment and may show others, situated in the same position, that ideal hospital facilities are not absolutely indispensible. An added objection to the "outpatient treatment" lies in the personnel of the clinic, which is composed to a large degree of people of more or less shiftless character. Because of this fact, a large percentage of our patients have disappeared. The fact that it has been impossible to trace such individuals is not only a waste of effort, but injures the value of such statistics by limiting the number of cases.

Appreciation is due to Dr. E. W. Taylor, Chief of Service of the Neurological Department, for stimulating advice and encouragement and to Drs. Henry C. Baldwin and Walter E. Paul, Neurologists of the Massachusetts General Hospital for valuable help in conducting this investigation. The complement fixation reactions, without which the work would have been of little value, have been performed by the Pathological Department under the guidance of Dr. James H. Wright, Director of the Pathological Laboratory.

This paper is in no wise a neurological treatise, but consists of a review of the definite results of a specific form of treatment upon diseases of the nervous system, the syphilitic character of which has been established in the light of our present knowledge. Erb[1] in 1881 suggested the connection existing in a vast majority of cases between tabes dorsalis and syphilis. But it was not until the discovery of the Spirochete pallida by Schaudinn and Hoffmann[2] in 1905 and that of the specific serum reaction by Wassermann[3] in 1906 that the definite connection between these diseases became an established fact.

* Read before the Medical Section of the Suffolk District Medical Society, Dec. 17, 1913.

It is not within the scope of this paper to discuss the varied forms of treatment for syphilitic diseases of the nervous system. The consideration is limited to the effect of salvarsan.

The results of treatment have been most varied. Leredde,[4] Ljass,[5] Collins and Armour,[6] Wechselmann,[7] and others have reported most favorable results. But as Jadassohn[8] points out, optimistic findings must be reviewed with great scepticism for two reasons. In the first place natural remissions are not infrequent in such diseases, especially in general paresis. Secondly, the enthusiasm resulting from the use of a new and much lauded drug is bound to have a beneficial result when employed in a chronic disease of long standing. Moreover, it is very common to see improvement in such cases from the use of any form of therapy which is attempted for the first time.

The benefits which have been witnessed in this group of cases is, however, of long standing and is maintained during a prolonged period during which the patient has received no treatment. As a further control, the serum and spinal fluid have been examined before and after treatment and, in as many cases as possible, at a period of at least six months after the last injection. These facts will be enumerated in detail in their proper order.

TABLE I.

CASES UNDER OBSERVATION IN THE NEUROLOGICAL CLINIC OF THE MASSACHUSETTS GENERAL HOSPITAL, AUGUST, 1911, TO DECEMBER, 1913.

Group.	Cases.	Treatments.	Lumbar Punctures.	Serum Tests.
Class A	24	107	42	63
Class B	6	27	4	14
"Spinous Cases" before spinous treatment	7	25	11	8
Lost cases	14	36	11	16
One injection only (lost)	9	9	6	9
Non-syphilitic	4	15	3	6
Total	64	219	87	116

The table shows the work performed in the clinic during the year and a half that new cases were received for this work. The lumbar punctures were performed to a large extent by Dr. James B. Ayer. In every instance he has enumerated the cell-content of the fluid and in some doubtful cases has carried out the Proteid Reaction. The technique of the "Wassermann reactions" has been uniform. The sheep corpuscle-rabbit-haemolytic system with a beef heart antigen has been employed.

The statistics are drawn from Class A, which consists of 24 patients who, having been followed for from 12 to 28 months, have reported within the last two weeks; Class B, consisting

of 6 patients, observed from the start, who have reported not later than June 1st, 1912, and lastly, a group of private patients as follows:

TABLE II.

PRIVATE PATIENTS.

	Cases.	Treatments.
Followed	19	62
Lost	8	9
Total	27	71

The entire group shows an aggregate of 91 patients, who have received 290 treatments. Attention is limited, however, to the three above mentioned groups with a total of 49 patients, with especial attention to Class A which has been controlled with much greater care and has been followed for a longer period than the others.

ETIOLOGY.

The syphilitic etiology has been demonstrated in 28 of the 30 cases of classes A and B, by means of history, complement fixation reactions in blood or spinal fluid, and by proteid reaction or cell-count in the latter. In one of the remaining an error in technique prevented an absolute conclusion, although the results throw much more than a suspicion on syphilis as a causal factor. The last case alone was absolutely unproved. For the sake of simplicity, the cases are divided into the following three classes: Tabes, General Paresis and Syphilis of the Central Nervous System.

TECHNIQUE.

Owing to the fact that our patients were forced to return to their homes following their injections, it was thought wise to administer small doses of salvarsan. With only rare exception 0.3g. salvarsan, in neutral solution, in 125 cc. of freshly distilled salt solution was introduced through the Schreiber needle, by means of rubber tubing attached to a 25 cc. Burroughs and Wellcome glass syringe, into the median vein. The ordinary means of asepsis were preserved. Care was taken not to introduce the fluid too rapidly and not to allow any of the drug to escape into the subcutaneous tissues. The use of such a small dose is considered inadvisable by Swift and Ellis,[9] but seems perfectly justified under the existing conditions.

CLINICAL RESULTS.

The accompanying table illustrates the clinical results in the simplest terms possible.

TABLE III.

Tabes Dorsalis:

	Class A	Class B.	Class C.	Total.
Improved	12	2	8	22
Moderately improved	1	0	0	1
Slightly improved	1	1	2	4
Not improved	3	0	2	5
Total cases	17	3	13*	32

* One case at present under treatment.

General Paresis:

	Class A	Class C.	Total.
Improved	1?	1	2
Not improved	2?	1	3
	3	2	5

Syphilis of the Central Nervous System:

	Class A	Class B.	Class C.	Total.
Improved	6	3	5	14
Slightly improved	1	0	0	1
Not improved	0	0	0	0
Total	7	3	5	15

Under the heading of tabes are classified three cases in whom there is a question of the existence of general paresis. Of these three, one alone has shown improvement. The other two, V and XIV, are suffering from disturbed mental states which have shown no change under treatment. The latter represent two of the three unimproved tabetic cases in Class A. The remaining individual (XI) is one with a long standing degenerative process in whom no good results from treatment could be demonstrated. The two unimproved cases in Class C (Nos. 384 and 558) fall into the same category as that just mentioned. The final results in tabes in this group show improvement in 27 cases or 84% and no improvement in 5 or 16%. Of the five unimproved cases of tabes, four have remained stationary and one has advanced. These figures include the two cases of questioned general paresis above mentioned. In no instance was any change in mental state noted in the latter disease. In one (VI), where that diagnosis was considered as possible, there has been a marked amelioration of distressing tabetic symptoms and in another (No. 445) there was decided improvement in strength on the side which had suffered paralysis. On the whole, the results from this small number of cases of general paresis are anything but encouraging. The reverse is true in cases of syphilis of the central nervous system. There, one hundred per cent. of improvement was shown in this group; and in only one instance (XVIII) could the change be called slight. The latter, a spastic paraplegic, complained simply of difficulty in locomotion. That a relief from this could not be considerable is not very surprising.

In addition to the failures in these tables and reviews, six cases have failed to show as much improvement as desired. Of these one had received two intra-venous injections, one three, three five, and one six. Two of these showed

moderate, but insufficient improvement; four showed not much of any change. All six were placed upon serum treatment. The results of this work are reported by Dr. Ayer.

The improvement in symptoms is a matter of considerable interest.

TABLE IV.

	Tabes.	Syphilis of C. N. S.	Total.
General Health and Strength:			
Marked improvement	17	10	27
Slight improvement	4	1	5
	21	11	32
Lancinating Pains:			
Improved	17		17
Apparently dispelled	8		8
	25		25
Ataxia improved (apparently from added strength)	8		8
Eyesight improved (diplopia, etc.)	4	4	8
Headache relieved	3	5	8
Vertigo relieved	3	2	5
Paralysis relieved	0	9	9
Gastric crises relieved	2		2
Urinary Control:			
Improved	1	0	1
Apparently recovered	..0	1	1
	1	1	2
Anesthesiae improved		4	4

It will be seen from the accompanying table that improvement in general condition and strength and gain in weight is nearly a constant result in all improved cases. The relief of lancination pains is also a most common and striking result of a thorough course of treatment. In many instances, the entire disappearance of such symptoms has been noted—in all eight in number. The relief of ataxia and improvement in gait is no doubt in most instances due to increased physical strength. Headache in syphilis of the central nervous system is almost always dispelled by the use of salvarsan. It might not be out of place to give a very brief review of a few striking examples of the relief of symptoms.

CASE 1. Helpless woman, suffering from syphilitic ataxie paraplegia of five years' duration. Urinary incontinence and lancinating pains for the last six months. Following treatment she has improved steadily. She is now doing all her own housework and never uses the cane when in-doors. She has gained 28 pounds and has no pain and no urinary incontinence. Her improvement has lasted for over a year.

CASE 3. Tabes, of five years' duration. Patient had severe lancinating pains and described himself as a cripple. Now he has no pains and "gets about without his cane." His improvement has been maintained for over six months.

CASE 8. Tabes, of nine years' duration. Patient suffered from lancinating pains, gastric crises and urinary incontinence. Following treatment, all of these symptoms disappeared and have not returned during the last year. For the last eight months she has worked (dressmaking) for eight to nine hours daily.

CASE 16. Syphilis of the central nervous system (basal). Patient had suffered for a year from diplopia, headache and vertigo, nausea and ataxia. Two months following the last injection, *i.e.* March, 1912, she was perfectly well. There has been no return of symptoms. She is now working five hours daily.

CASE 19. Syphilis of the central nervous system (spinal). Patient was suffering from an acute, advancing paraplegia. There was well-marked paralysis and pain in the right leg. The left was becoming weak. Urinary incontinence. Nine months after his last treatment the right leg is much stronger and free from pain. The left leg is absolutely normal. Bladder incontinence remains the same, however. Marked improvement in general condition.

CLASS C.

No. 213. Syphilis of the central nervous system. Right-sided hemiplegia with difficulty of speech. Headache. Duration of symptoms two weeks. Following treatment all the signs and symptoms began to clear. Now, two years later, he is "as well as ever."

No. 517. Syphilis of the central nervous system. Cerebral thrombosis. Complete left-sided paralysis. This had persisted for a week without much improvement. Following treatment he began to improve at once and now (six months after his seizure) he is as strong as before.

It is, of course, impossible to state what would have been the progress of cases 213 and 517 without treatment. The results are very suggestive, however.

No. 326. Syphilis of the central nervous system. Headache, diplopia and numbness of legs of a year's duration. Patient was such a sufferer that she was incapacitated. Following the last injection all symptoms disappeared and for the last ten months she has done all her own housework.

No. 511. Syphilis of the central nervous system. Headache and transient diplopia for three years. Hemianesthesia and hemiparesis for six months. His strength and sensation returned gradually during his course of treatment. Before his last injection he reported that he had just "chopped down a tree one foot in diameter." His improvement has been sustained for the last six months.

No. 334. Tabes, of one to two years' duration. Lancinating pains, gastric crises and bladder disturbances. Pains and gastric symptoms responded almost immediately to treatment. Now, seventeen months after his last treatment, he feels perfectly well. No return of old symptoms, no new symptoms developed.

This brief case review presents simply the most striking clinical results. Not all symptoms are relieved in every patient and in the five noted in Table III no improvement of any note could be found. The six cases placed on serum treatment should also be considered as unsuccessful. In spite of the extensive improvement in symptoms, not a single change in physical signs has been discovered, save in regard to

biological and cytological changes about which mention will be made at once.

BIOLOGICAL AND CYTOLOGICAL CHANGES.

The accompanying table, based upon Class A, shows the changes that have taken place in the complement fixation reactions upon blood and spinal fluid and in spinal lymphocytosis. In many intances, patients have refused to be submitted to lumbar puncture, after suffering enough reaction from their first to incapacitate them for work 24 to 48 hours.

Seventeen of the 24 cases of Class A show changes in the serum or spinal fluid fixation reactions or cells counts. Spinal fluids show changes in 10 or 42%; blood in 9 or 38%. Both are altered in two cases. This shows a high percentage of physical alteration due very evidently to the treatment and persisting in many cases for months after the last injection. The most striking conclusion from these figures is obtained from a comparison of these biological and cytological changes with the clinical results already referred to. See table VI.

TABLE V.

	Before Treatment.			After Treatment.			9 to 15 Months After.			
	Blood.	Sp. Fl.	Cells.	Blood.	Sp. Fl.	Cells.	Blood.	Sp. Fl.	Cells.	Improvement.

NOTE: O = No change (Improvement). + = Change (Improvement). — = No observation.

* Negative examinations before treatment. No. V thrown out through error in technic.

Six cases failed to show any biological or cytological improvement following treatment. It will be noted that cases II and VII had blood reactions only performed; and in both instances the primary results were negative. These might well be excluded from consideration. Of the remaining four which alone failed to show expected change, one presented only moderate improvement clinically, one slight change for the better and one no alteration in his condition. Hence in only one case which was clinically improved was there no change reported from laboratory examination. This patient (XXIV) showed no diminution in the intensity of his serum reaction. It was impossible to get consent for a second spinal puncture. In none did an improvement in reaction or cellular content of the spinal fluid occur without betterment of the clinical condition of the patient. In only one case (XIV) was there a change in serum reaction in a patient showing no physical improvement, hence, from this series, it appears that as an indication of clinical improvement the diminution in intensity of the serum reaction is of considerable value, but that that of the spinal fluid and especially that of lymphocytosis is in every instance a correct index.

DURATION OF IMPROVEMENT.

The accompanying table (No. VII) shows a detailed study of the improved cases of Class A in relation to the length of time that they have maintained their gains since receiving their last treatment.

TABLE VII.

TABES.

Months.	Cases.	
22	1	
20	2	
19	1	4 cases over 18 months
17	1	
13	1	2 cases from 12 to 18 months
11	2	
10	2	
9	1	5 cases from 9 to 12 months
4	2	
3	1	3 cases from 3 to 9 months
	14	

SYPHILIS OF THE CENTRAL NERVOUS SYSTEM.

Months.	Cases.
24	1
23	2
11	2
9	2
	7

The Table may convey an erroneous conclusion since in many instances patients have returned for further treatment without any relapse from their improved state. As a matter of fact, it is of great advantage for the patient to return at intervals even though in improved health to receive further treatment. If the somatic disease syphilis requires years of treatment for its eradication, it is rational to suppose that its elimination from such deep-seated structures as the cord, brain or meninges would require quite as long, if not a longer time.

All cases were received with care January 1, 1913. At that time one case was reported as improved (V), who now seems to show no change from his original condition. One case reported at that time as unimproved is now moderately benefited. These facts further emphasize the necessity of proper control through laboratory observations. In no other instance has there been a sufficient alteration in the patient's condition during the 11 months to warrant any change in classification.

TABLE VIII.

IMPROVEMENT IN TABES IN RELATION TO DURATION OF NERVOUS PROCESS.

Improved Cases.

Duration of Tabes.	Cases.
9 years	1
7 years	1
5 years	2
4 years	3
3 years	1
2 years	1
1 year	2

Moderately Improved.

1 year	1 case

Slightly Improved.

1 year	1 case

Cases Showing no Improvement.

Duration of Tabes.	Cases.
9 years	1
5 years	2
Total	3

These figures show the unimproved cases to be of long duration. But on the other hand, many of the cases which showed the most striking benefit from salvarsan had been in progress five years or over. But one fact remains, that all the cases in this group, except those presenting paretic mental symptoms, which have shown slight or no improvement, have been those in whom advanced degenerative lesions existed before treatment. The cases of syphilis of the central nervous system, which have been benefited the most, have harbored the disease the longest. It is difficult to explain the reason for this peculiar fact.

A review of the tables fails to show any relation between the degree and speed of improvement and the date of initial syphilitic infection. Those who have harbored syphilis in the body for the longest periods seem to be as susceptible to improvement as those more freshly infected.

Persistence in treatment is essential for its success. Two injections are seldom of any lasting service. Although the greatest improvement is generally noted after the first or second administration, yet in the improved cases continuous progress is as a rule the result of repeated treatments. It seems wise to advise injections at one to two week intervals until six or eight are taken. Then it might be well to carry out series of two or three injections at six to eight week intervals, as Leredde advises.

Two of the unimproved cases were persistent in seeking relief, one receiving six and the other eight injections. Many showed improvement after only three or four doses, rarely one after only two. But the majority of those who adhered closely to the treatment have shown improvement. As is the case with syphilis elsewhere, treatment should not cease upon alleviation of symptoms. It has been impossible, however, to impress this fact forcibly enough upon the minds of most of this class. It is undoubtedly true that the results of this work would have been more satisfactory, had patients been willing to return for further treatment although for the present relieved.

REACTIONS.

To the thirty members of Classes A and B, 134 intravenous injections of Salvarsan have been administered. Reactions, consisting of chills, nausea, vomiting and fever followed five injections. All reactions followed either the first or the second injection and lasted from 24 to 48 hours. In a few instances the reaction was delayed from 24 to 48 hours, as is not unusual in cases of this variety.

An extensive hematoma developed after one injection (XXI, which lasted for ten days. In two instances (XXIV and XXVII) a thrombosis followed one of the injections. Both attempts to introduce the needle directly in Case 1 failed and the vein was exposed. This is a fault to be avoided if possible, first because of the added complexity of the operation, secondly because the scar acts as tell-tale evidence, and, finally, because the vein exposed is necessarily unfit for subsequent use. This is a matter of considerable importance when frequent injections are contemplated. There were no other ill effects and no other difficulties in administration than those mentioned.

One man, who had been lost from observation, has been reported dead—cause unknown and not determinable.

HERXHEIMER REACTION.

The exaggeration of symptoms provoked by the administration of salvarsan is considered to be a modification of the so-called Herxheimer reaction. It is the opinion of Erlich and others that the parasiticidal action of the drug serves to liberate imprisoned spirillae or their toxines situated at the focus of infection. Whatever the cause, it is true that lancinating pains and gastric crises in tabes and headache in cerebral syphilis are very prone to be accentuated by the first treatments, when those symptoms are at all prominent. This reaction lasts for 24 to 48 hours or even as long as a week in some instances, but eventually passes away. Cases IX and XX suffered pronounced reaction of such a sort, the latter following all three injections, but being most pronounced after the first. The presence of such a modified Herxheimer reaction should be looked upon as a relatively hopeful sign, since in those cases the particular symptom which is so accentuated is often eventually relieved.

PROGNOSIS.

It is extremely difficult to foretell the result of this treatment. As has been shown, it is more than reasonable to hope for a consider-

In bed a week. Arm stiff and lame	21 ii 12, arm became stronger after first injection. 14 iii 12, speech, gait and headache much improved. 28 v 13, headache, vertigo, gait and sight remain improved. General condition improved.

able degree of symptomatic relief. It is also evident that in many instances the course of the disease is for the time being, at least, checked. Many of the cases which showed negative fixation reactions in serum and spinal fluid prior to treatment have shown symptomatic relief. The cases as a rule in whom there was slight or no improvement, on the other hand, have shown primary reactions of only moderate intensity. The most striking fact is the marked improvement in cases, in whom biological and cytological examinations revealed intense syphilitic reactions. As might be expected, the results of anti-syphilitic treatment are more pronounced in those cases in whom the syphilitic element is most intense.

CONTRA-INDICATIONS.

Advanced cardiac disease, especially of myocardial origin, has been cited as a warning against salvarsan treatment. One case in Class A (V) falls into this category. He received three injections, however, without ill effect. That the heart became decompensated six months following his last injection shows the severity of the cardiac lesion and the apparent safety of salvarsan in this particular instance.

Two cases (Class C, 240 and 416) suggest a contra-indication which has received scant attention in the literature. Neither patient presented symptoms or signs of pulmonary tuberculosis prior to injection. Both developed active processes after their first and only treatment. In one, cough and fever appeared and tubercle bacilli were found in the sputum. The other had an haemoptysis. At the present time it is impossible to locate either patient. What may be a coincidence deserves consideration in the future.

CONCLUSIONS.

The following conclusions seem warranted:

(1.) The syphilitic character of the process was proved, with one exception, in all the cases upon which this work is based.

(2.) It is possible to treat in a satisfactory manner syphilitic diseases of the central nervous system by intravenous salvarsan in an ambulatory clinic.

(3.) Small doses of the drug are necessary for this purpose, but such dosage yields results.

(4.) With the exception of the six cases placed subsequently on serum treatment and excluded from this paper, symptomatic improvement has resulted from thorough treatment in a high percentage of cases of Tabes and in all cases of Syphilis of the Central

Nervous System. No distinct improvement has resulted from treatment of the few cases of General Paresis under observation.

(5.) Improvement in strength and gain in weight is the rule in those who receive benefit. The relief of lancinating pains in Tabes, and Headache in Cerebral Syphilis is most striking.

(6) Biological and Cytological Changes (in blood and spinal fluid) indicate that there is an organic basis to this symptomatic improvement. It is regrettable that those observations were of necessity so limited.

(7.) Improvement has been maintained over a long period of time—in many instances for from one to two years. The results of laboratory investigation when obtainable and the amelioration of symptoms correspond.

(8.) Whereas the failures have been in old-standing cases, it is impossible to show any constant relationship between the degree of improvement and the duration of the nervous lesion.

(9.) The most striking improvement follows the first or second injection. Treatment must, however, be persistent and prolonged and should be continued even if all symptoms and laboratory findings have long disappeared.

(10.) Reactions are infrequent with small doses of the drug. Accidents are rare.

(11.) Focal accentuations of symptoms (Herxheimer) disagreeable, but of short duration. These are often a hopeful sign.

(12.) The most pronounced successes are in those who show evidence in blood or spinal fluid of intense syphilitic infection. The failures have occurred in those showing feeble reactions.

(13.) Phthisis seems worthy of consideration as a contra-indication.

(14.) This treatment might well be advised in all cases of syphilitic disease of the central nervous system and abandoned for the serum treatment when conscientious effort in this simple and safe procedure has failed.

NOTE: Hearty thanks are extended to Dr. F. B. M. Cady for assistance in the administration of salvarsan and to Dr. A. R. Kilgore for the performance of the luetin test.

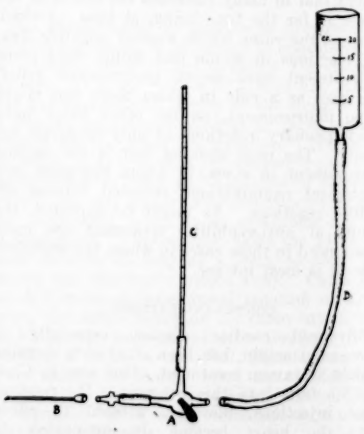
SALVARSANIZED SERUM ("SWIFT-ELLIS TREATMENT") IN SYPHILITIC DISEASES OF THE CENTRAL NERVOUS SYSTEM.*



BY JAMES B. AYER, M.D., BOSTON,

Assistant in Neurology and Neuropathology, Harvard Medical School, and Assistant Neurologist, Massachusetts General Hospital.

[From the Department of Neurology, Massachusetts General Hospital.]

WHEN syphilis involves the cerebro-spinal axis physicians realize that a condition exists which is always resistant to treatment. To be sure symptomatic relief not infrequently occurs from a moderate amount of medication, but the conscientious physician understands that a cure has not been obtained; in fact the feeling has come to be a certainty that this form of syphilis, more than any other, does not die, but only sleeps, if indeed a repeatedly awakening process can be said to sleep.

Up to a few years ago the chief armamentarium of the neurologist in combatting these diseases was mercury and the iodides, and in the acute exacerbations of these conditions, whether the palsy of an active syphilitic condition or a sudden increase of pain in the tabetic, these remedies were used with greatest effect. The subject of general paresis, however, was looked upon as incurable from the

beginning, and an absolutely bad prognosis made in his case. With the advent of salvarsan a new hope appeared, and in many cases has been realized in the treatment of these affections, as Dr. Spooner's article clearly shows; but along with salvarsan therapy has come the frequent use of laboratory means of testing our patients until it has become only too clear to anybody working with these cases that there is a vast difference in relief of an individual symptom and a cure of the disease. Salvarsan given intravenously has done much good, it almost always does as much good as the older treatment, frequently does more, but in the light of modern methods of control, rarely can be said to cure.

It was with a view to reaching the cases refractory to other forms of treatment and if possible to cure syphilis of the central nervous system that Swift and Ellis commenced, two years ago, their method of subdural injection of salvarsanized serum [1], [2], [3]. Their method presupposes living spirochaetes as the infecting agent, harbored in the lymphatic system and interstitial substance of brain and cord, and supposedly cut off from the blood stream, and therefore not to be reached by drugs which cannot pass into the spinal fluid. It is not only a means of putting salvarsan into this isolated region, but salvarsan in its most effective form, namely, in combination with serum, for it has been clearly pointed out by Ehrlich[4] that salvarsan without the presence of serum is not anti-spirochaeticidal. As a matter of fact the quantity of salvarsan that reaches the spinal canal by this method must be so minute that it is logical to trace benefit from the treatment to the serum which has been acted upon by the salvarsan in vivo than to the drug itself.

The technique which the originators have recommended and to which we have adhered in all essentials is as follows:—one hour after an intravenous administration of salvarsan about 40 c. c. of blood are drawn under aseptic conditions and allowed to clot; the following day the serum is taken off and mixed with normal salt solution to make 30 c. c. of a 40% strength of serum, this heated at 56° C. for ½ hour and put into the spinal canal, replacing spinal fluid withdrawn.† It will readily be seen that in the carrying out of this technique frequent opportunity is given for laboratory control of the progress of treatment, so that in every case dealt with we have a double standard to guide us the clinical symptoms and signs and the laboratory findings in blood and spinal fluid.‡ To bring about symptomatic improvement and even a seeming cure is frequently an easy matter, but to also reduce the spinal fluid to a normal appearance is always a more difficult task, yet necessary before we can claim a bona fide "cure."

The following 18 cases represent the experience of 13 months with serum therapy, although the cases for the most part have been observed for a much longer time. Generally the patients under discussion were placed upon serum treatment because refractory by one or both of the standards above considered, to other forms of therapy. Improvement in them should therefore be fairly attributed to salvarsanized serum; failure to improve, on the other hand, cannot be laid solely to this form of treatment, but must be shared with the others.

† See page 461 for Tests. ‡ See page 461 for Methods.

THE GROUP OF TABES.

PATIENT No. 1, V. S. is a tabetic with the usual symptoms and signs of this disease. He was benefited somewhat by intravenous salvarsan, but we thought to hasten this improvement by intraspinous injections, of which he has received nine with benefit as regards pain, bladder and general condition and to a less extent his walking. Symptomatic improvement has unquestionably proceeded more rapidly in the last 6 months under serum injections than in the previous 6 months under intravenous salvarsan alone.

The laboratory findings, however, have not varied greatly in the past three months, and we have been so far unable to reduce his spinal fluid to normal according to any test.

No. 2. R. J. O'N. had typical symptoms and signs of advancing tabes, pains and difficulty in walking, rendering him useless. He received five intravenous salvarsan injections without benefit either symptomatic or from a laboratory point of view. He was then given serum injections, eleven in number, throughout this year with marked benefit. His pain is now almost confined to a period 48 hours following injections and there is coincident improvement in his spinal fluid.

No. 3. A. F. Y. suffers principally from gastric crises, the intervening time between which was lessened by intravenous treatment from two week intervals to two month intervals. We are now seeking to still further better his condition by the use of serum, of which he has received five injections with no material change in condition.

CASE No. 4. J. J. C. is a motorman with symptoms and signs of tabes, the former extending over a period of 17 years. Salvarsan given by vein did not help him either from symptomatic or laboratory point of view; but a year's course of serum therapy, including 7 injections, has at last made him pain free, and tests normal, even using the strongest antigen on the spinal fluid. He will be carefully watched for evidence of relapse.

These four cases are of the hopeful type, showing primarily evidence of lower spinal cord involvement in an active stage as demonstrated by positive laboratory tests. The three treated for sufficient length of time to judge show improvement, and two of these have responded promptly and well to spinal injections after all other methods had failed.

The next two belong to a group which has been designated "atrophic," with evidence of little or no activity from the laboratory point of view (perhaps because of insufficient delicacy of these tests), though still having severe pain. Both cases are of some 20 years standing.

CASE No. 5. Mr. S. received only two injections and claimed his pains were worse, too small a number to judge of the value of the treatment.

CASE No. 6. S. has thus far received three injections and while the pain continues with nearly the same frequency—namely, one attack a day—it is less severe when present. His bladder has recovered considerable tone. He has also gained 10 pounds in the last month and is in every respect more comfortable.

Two cases of tabes presenting progressive primary optic atrophy were treated as follows:

No. 7's eyes were rapidly undergoing atrophy, in spite of intravenous salvarsan. We hoped with serum treatment to stop the process, but only succeeded in slowing it a little, the patient having gone on to almost complete blindness. On the other hand he has showed marked improvement in general condition, so much so that he wished to continue treatment for this effect. With him we see little change in the serologic tests.

No. 8. G. A. P.'s optic atrophy was more slowly progressive. In spite of two courses of intravenous salvarsan (in all 9 doses of .3 gram each), and much mercury over a period of eleven months, vision progressively failed, with serum during the past four months—7 doses in all—the atrophy does not seem to be advancing, and laboratory tests have improved greatly.

SUMMARY.

Eight cases of tabes were dealt with, falling naturally into 3 classes: Nos. 1, 2, 3, 4 giving evidence of lower spinal cord disease in an active stage, 5 and 6 active as regards symptoms, but quite inactive to our laboratory tests; the third class, Nos. 7 and 8 "superior tabes" in which primary optic atrophy was the reason for undergoing treatment.

IN CLASS 1, lower cord tabes active both clinically and to tests, 3 cases, treated for a long period of time have received marked symptomatic relief, pains, bladders, general strength and weight all improved. Signs have not been seen to change. From the laboratory point of view marked benefit, in one case going to a negative Wassermann in the fluid tested with the re-enforced antigen. The fourth case of this class has shown no change in any respect as yet on five injections.

CLASS 2 contains two cases of long-standing tabes of some 20 years duration. No marked change was anticipated in them because of the inactive condition of the fluid, so that when one patient (6) increased in weight 10 pounds in 30 days and declared his pain was benefited we were agreeably surprised.

CLASS 3, the optic atrophy cases, have been the most resistant to treatment. Of the two in our series one (7) has continued his course to blindness with hardly any moderation in rapidity, and no change in laboratory tests. The second (8) with much more slowly progressing atrophy is holding his own as far as sight is concerned, with improvement in laboratory tests. It has been said that optic atrophy is contraindication to the use of salvarsan, but we have used it now in 18 cases, without any increase in rapidity of the process, and with, I believe, benefit in several. The majority, however seem not to be affected one way or the other.

Four cases may be grouped under *general paresis*, but in two the diagnosis may well be questioned. As others, [5], [6] had spent much time on advanced cases, with not too satisfactory results, we determined to try only early ones, so early in fact that in two we hardly feel justified in making an absolute diagnosis.

No. 9. L. W. B. 14 years after his primary infection, showed evidence of mental disturbance, with hallucinations of sight and delusions (though not of grandeur) so that confinement was necessary, but with negative physical signs. He had positive laboratory tests throughout. He has responded somewhat to treatment, his wife noting much improvement in his actions. His tests improved while under treatment, but relapse, in the laboratory sense, promptly followed cessation of injections, as will be seen in his chart.

No. 10. Mrs. L. T. has had typical epileptiform seizures, and has besides Argyll-Robertson pupils, but when taken in hand had no mental stigmata of dementia paralytica. She however continued to have her epileptiform attacks and later developed hallucinations and delusions, and commitment became necessary. It is interesting to note that in her case the reaction to the medicine was not one of pain, but either no reaction at all, or occasionally a production of hallucination of sight and hearing.

No. 11. H. C. D. was unequivocally diagnosticated general paresis by the neurologist referring him for treatment on the basis of epileptiform seizures, dizzy attacks and mild mental disturbance coming on 8 years following a chancre. Physical examination has always been negative, but laboratory tests all positive except that the blood is positive only to the stronger antigen. He is undeniably much better for treatment, as evidenced by his appearance, his capacity for work, his actions and his entire freedom from epileptiform attacks since starting treatment. From a laboratory standpoint also he has shown steady benefit from the injections. Like case 9 symptomatic relapse was accompanied by "laboratory relapse" when treatment was discontinued for six months.

No. 12. A. M. S. is a girl of 7 years, syphilitic from her first year and exhibiting for over a year epileptic attacks, mental restlessness and gen-

eral mental backwardness. She has inactive pupils, as her sole physical sign of syphilis of the nervous system. In two respects she has benefited by treatments;—she now has no epileptic seizures and she is neater and cleaner in her habits; even the neighbors, harsh critics of children, admit this. The treatment of this case was necessarily carried out in a different manner from the others. Inasmuch as she had very small veins we were forced to use a foreign serum. The first six injections were with blood obtained from her father in the usual manner, he, however giving a negative Wassermann test and unquestionably not suffering from active syphilis in any form. The last four injections were with serum obtained from tabetics under treatment on the same day.

SUMMARY.

The influence of salvarsanized serum has been distinctly less beneficial in this group than in either the foregoing or subsequent group. All have shown amelioration of laboratory findings, and supposedly therefore diminution of activity of the syphilitic process. This laboratory improvement has however come with greater difficulty than in any other group; nor has it been so constantly parallel with symptomatic improvement. One undoubted case of general paresis has proceeded to a worse condition without material modification in the course of the disease (10); but in two epileptic attacks have ceased, though in one of these petit mal seizures seem to have replaced the more severe ones.

No. 13. Miss N. R. may best be classified in a group which is gaining in recognition, perhaps best called *"latent nerve syphilis."* She shows no true stigmata of general paresis, yet her symptoms are referable more to brain than cord; a typical Argyll-Robertson pupil and occurrence of symptoms probably seven years after infection clearly take her out of the class of so-called cerebro-spinal syphilis. We feel that she is a candidate for general paresis, but cannot certainly place her in that category. She has as yet had only 4 serum injections but symptomatic and laboratory improvement is already observable. It is in this group of cases, difficult of diagnosis frequently, in which we may expect much from intensive treatment.

The last group, admittedly the easiest of all to help, even with older forms of treatment, is that of *cerebro-spinal syphilis*, with a latent period of months or only a few years at most. In all of these we see marked benefit and in them we may, if in any, hope for a cure.

No. 14. A. C. had an unconscious attack about a year following his primary lesion. He was later found to have choking of both optic nerves and positive laboratory tests. Intravenous salvarsan helped him, but we thought to clinch its beneficial results with serum treatment, and so far we have met with success. He was discharged in October clinically well, and tests almost perfect. Three months later he reported on request, still without symptoms and his spinal fluid still further improved; the Wassermann reaction and cell count became normal first, later the proteid tests all became negative (Noguchi, Nonne and alcohol), but we find the Lange gold test alone evidence of his syphilitic infection.

No. 15. V. Z. denies syphilitic infection, but presented himself with a history of failing sight for eight months past, and headache. He showed double optic neuritis, concentrically contracted fields and complete internal ophthalmoplegia. Intravenous salvarsan relieved symptoms and the optic neuritis, but ophthalmoplegia and tests remained positive. Serum administration has greatly improved the fluid findings; and on my last examination on Dec. 1st. the accommodation reflex in the left eye was found to have returned.

No. 16. W. E. N. is a case of cerebral "neuro-relapse." In spite of (or "because of" as some say) five salvarsan injections, mercury and iodide, he developed a cerebral syphilitic process; for three weeks he had a temperature and pulse record closely simulating typhoid. He was benefited by more salvarsan and two serum injections, but on June 20th. while away from the hospital on leave of absence he had a shock leaving him paralyzed on the left side. At this point I was asked to see him, recommending, much to the disgust, I fear, of one physician, more serum injections, arguing that he had done well on those which he had received, but that he needed more of them. He has, as his chart shows, done well. his complaints are none, except that he cannot find work to do, and the condition of his fluid is greatly improved. In spite of freedom from symptoms he is of course not cured.

It is interesting that here laboratory evidence of syphilis has disappeared more quickly in spinal fluid than in blood, unlike the case with long-standing involvement of the cerebro-spinal axis.

No. 17. W. B. B. is another case of "neuro-relapse," this time the cord being the objective point. His walking, progressively more spastic when serum treatment was begun is now nearly natural, and a bilateral ankle clonus which was present has disappeared, although Babinski's sign still remains on both sides. His tests also coincide with his clinical improvement.

No. 18. J. D., the last of these cases is a particularly interesting patient. Since his first injection of salvarsan by vein, after which his only symptom, headache, disappeared, he has belonged to the class of "latent nerve syphilis." He might have been discharged after one injection to testify to the great efficiency of the one-dose treatment. But unfortunately for his peace of mind we were enabled to show that he had much trouble still present and repeated treatments hardly benefited the tests. After five intravenous injections, it was determined to try the effect of serum treatment on his tests (for all this time he had no symptoms or signs of disease other than the laboratory findings.) A prompt response was the result and five injections improved the fluid to a considerable extent, when the patient was forced to leave town for the summer. During the three

TYPES OF REACTION.

months following he was perfectly well, but on October 1st. to our astonishment the fluid had returned to nearly its original state. Again the condition and possibilities of future trouble were explained to him and again he has submitted himself to our attempts to eradicate a condition which bothers him not at all, but which, we feel, is a constant source of danger to him. This case more clearly than any other shows the efficiency of salvarsanized serum in attacking the pathological process, where salvarsan alone had failed; again laboratory relapse when treatment was discontinued is followed by improvement again with treatment resumed.

SUMMARY.

Summary of these five cases of active cerebrospinal syphilis shows improvement according to all the standards we have set up, symptoms, signs and laboratory tests. The critic, however, will rightly suggest that this group usually does very nicely with other treatment. He will also admit that some do not, and, as a matter of fact 4 of these 5 cases were chosen for serum therapy because resistant to other forms of treatment. Thus No. 15 showed symptomatic improvement from salvarsan administered by vein, but the use of serum treatment was promptly followed also by laboratory changes for the better. Again two cases of "neuro-relapse" occurred while the patients were under intravenous salvarsan, mercurial or iodide therapy; and serum treatment alone seemed efficient to stop the process. Patient No. 18 showed no laboratory improvement from intravenous salvarsan and KI, but when placed upon serum treatment improvement commenced; in spite of mercury (which was poorly tolerated) this improvement could not be maintained, a "laboratory relapse" setting in, which seems, however, to be again controlled by salvarsanized serum.

DISCUSSION.

The cases under discussion form a small number from which to generalize, as to the efficiency of a given treatment; still, more can be argued from these than from a hap-hazard group of 18 cases in that they are for the most part selected cases; they were largely chosen because of unsatisfactory results from other forms of therapy. Of these 18 cases then, representing a variety of types of syphilis of the nervous system, more or less refractory to other treatment, we find 14 distinctly improved, one unchanged, and three continuing on their course essentially unchanged. Of the four not benefited, two fall into the category of general paresis, two of tabes. Of the latter one showed a rapidly advancing optic atrophy, taken when sight was already far gone, the other was a long-standing case of the "atrophic type."

Of those benefited, the improvement for the most part has been striking, but seldom rapid. Improvement has for the most part been slow, but steady; those who have been persistent in treatment are those who have almost always obtained the most benefit; it has been striking and often gratifying to see patients return again and again for injections, without any urging; even those who underwent the most severe reactions were unremitting in their attendance, and this alone testifies to the good they felt they derived.

The above charts represent 219 venous injections of salvarsan or neo-salvarsan, and 126 serum injections. Of all these we have seen no harmful effects, other than the "reaction," below considered. True, we have persistently used small doses, .3 gm. of salvarsan and 30 c. c. of a 40-60% strength serum; we should have preferred to use larger doses, but as the patients were necessarily mostly ambulatory as far as the venous injections were concerned we could hardly do otherwise.

The reactions obtained are interesting. Tabetics almost always have severe pain, sometimes confined to the legs, frequently over the entire body. Two tabetics in particular would commence their reactions at a set time, one 3 hours the other 1½ hours after the serum injection, and with each pain the muscle bundle in the region affected would quiver as if stimulated by an electrode, first in one part, then another. These reactions last from 24 to 36 hours, and frequently are accompanied by rise of temperature, and less frequently of pulse also, there being no increase of the blood leucocytes (see charts.) Reactions in the other cases, one of superior tabes, the other a paretic, were quite different; these did not complain of pain, but on several occasions became hallucinated. One said "I see the trees looking short and the room all out of proportion. I hear voices speaking to me and yet I know it is not right." Again this same patient had bad dreams the night after an injection. Some patients on the other hand had no reaction at all. One, No. 18, a chauffeur, would take his car out three hours after an injection time and again, and never would feel any effects from the treatment. Naturally, some hesitation was felt concerning the use of foreign serum in the case of patient No. 12, but the only ill effects noted from this procedure was an urticarial eruption on one occasion similar to that obtained from the use of antitoxin.

Our *conclusions* then from the use of salvarsanized serum, a procedure so ably elaborated by Swift and Ellis, are these:

The method is safe.

It is effective in many cases where other treatment has failed.

It undoubtedly attacks syphilis from the etiological point of view, thus tending to cure the disease as well as relieve symptoms.

Its greatest effect is in the group of cerebrospinal syphilis, in which a cure may confidently be looked for in some cases with persistent treat-

ment; second, in tabes, in which arrest of disease process is often possible by this means; least effective in general paresis, when well developed, though here if taken in the pre-paretic stage encouraging results may be obtained.

With the originators of the method, we agree that persistence in its use is the key-note to success in the use of salvarsanized serum; consequently an estimate from the injection of one or two doses is a judgment more of the "reaction" which in some cases is severe, than of the therapeutic effect of the serum.

With the technique of administration and necessary control examinations as laborious as at present, we do not expect to see this form of treatment in general use, but believe it should be employed by those especially trained when other treatment fails in whole or in part, or in cases where haste is required in order to save vital tissue.

I wish to express my thanks to Dr. E. W. Taylor, chief of the neurological clinic at the Massachusetts General Hospital, through whose cooperation this work was possible; also to Drs. H. C. Baldwin, W. E. Paul and G. A. Waterman for encouragement and cases both in hospital and private; also to Drs. Swift and Ellis of the Rockefeller Institute for going over technic and protocols with me.

† LABORATORY TESTS.—The following technic in carrying out laboratory tests was employed in the spinal fluid: Cell count by means of the Zeiss cell counting chamber, using Zappert-Ewing ruling. A stain (methyl violet 6.1, acetic acid 2.0, water 50.0), drawn to mark 1 of the "white counter," and spinal fluid to 11, *immediately* after withdrawal of fluid from body; 1 cmm. counted on two slides and correction made for dilution. An accurate differential count is not possible by this means, but a rough index of the kind of cells present is possible, and these are almost invariably mostly lymphocytes. Proteid tests: (1) ethyl alcohol precipitation gives a rough index of the amount of coagulable proteid present, though normally there is some clouding. (2) Noguchi globulin reaction; 0.2 cc. of fluid + 0.5 cc. of a 10% butyric acid solution in normal saline boiled, and 0.1 cc. of a normal NaOH solution added and again boiled; a precipitate indicates a pathological condition of the spinal fluid. (3) Nonne's Phase I reaction; equal parts of fluid and saturated solution of ammonium sulphate to form a ring of precipitated proteid at their junction in a pathological condition. These tests have not all been performed on a given fluid; in fact it is only recently that I have begun to use the last-named as a routine procedure. Wassermann reaction performed at the Havard Medical School under direction of Dr. W. A. Hinton, and the Massachusetts General Hospital, under direction of Dr. Homer Wright until three months ago using the following antigens: (1) heart, (2) syphilitic liver of foetus; more recently a heart antigen reënforced with cholesterin; 0.5 cc. fluid used in each instance. Blood. Wassermann as above, using 0.2 cc. serum.

‡ METHODS OF ADMINISTRATION OF SALVARSAN AND SERUM.—First, salvarsan, rarely neosalvarsan, given in the usual manner intravenously. It is quite necessary that the salvarsan be given without cutting to expose the vein, inasmuch as many injections are required. Second, blood withdrawn either by means of a syringe and transferred to a sterile test tube or drawn directly into the tube by means of a suction apparatus. Third, serum pipetted off next day, mixed with saline to 40%, 50% or 60% strength as the case allowed and heated in water bath at 56° C. for one-half hour.

Fourth, lumbar puncture under cocaine anesthesia with the apparatus shown in cut. By means of a 3-way stop-cock the normal pressure is obtained, fluid is then allowed to escape by turning cock until the pressure has been reduced to about 40 mm. or until 20 cc. have been obtained, the serum is then allowed to flow in by gravity from a height not exceeding the pressure of the fluid as originally determined. By simply turning the stop-cock and thus connecting manometer with spinal canal the pressure may at any time during the flow be measured, and the rapidity of flow be controlled so that the pressure may be very gradually re-established. It is usually found that 30 cc. of serum may be injected to replace about 15 cc. of fluid withdrawn if plenty of time, 5 to 10 minutes, is taken at this step, which will leave the pressure the same as at the beginning. If done properly this whole procedure is of no inconvenience at all to the patient after the first puncture of the cocaine needle. The after-effects are either (1) reaction to the medicine, or (2) some headache and nausea, which not infrequently follow any lumbar puncture, no matter how carefully carried out.

EPICONDYLITIS (FRANKE) OR TENNIS-ELBOW.

BY WILLIAM PEARCE COUES, M. D., BOSTON.

This interesting affection first described by Bähr[1] in 1900 and later by Clado[2] and Franke[3], though known by some physicians, has not been described or studied in America to any great extent. Many diagnoses have been made of the condition such as "bursitis of the elbow," "neuritis," sprain, and functional disability from over-use. The injury leading to the disability is not uncommon in those who take much physical exercise, particularly lawn-tennis, whence the name: "tennis elbow." As will be shown later, however, athletic sports in which strenuous and exact movements of the arm play an important part, are not the only causes of the trouble. The history of the affection in those in whom it occurs in the course of their favorite exercise is almost invariably as follows: Immediately after a stroke, or occasionally some few hours or days afterwards, pain is noted in the elbow, usually the right, in the neighborhood of the external condyle. This pain may be so severe and sudden as to seem to paralyze the arm temporarily, so that all movements are performed with the greatest difficulty or not at all. This pain is usually markedly increased by extension of the forearm, not so much by flexion and may be intermittent or constant, and returns immediately the exercise is taken up again. Lesser degrees of pain and disability are noted in many cases. The pain is most sharply limited to the neighborhood of the external epicondyle of the humerus.

Examination soon after the injury usually shows no marked swelling of the elbow and no ecchymosis. The motion of the elbow is not as a rule limited in flexion or extension; but there may be great pain on forced extension in the neighborhood of the external condyle. The radial head is found to rotate perfectly. Pronation and supination are usually performed without pain. In short, the examination would seem to certainly rule without any marked bony lesion

or fracture. On pressure, an exquisitely painful spot the size of a dime, is found directly over the external epicondyle. Much pain is felt in this spot on full extension of the forearm, which radiates down the arm to the fingers. The pain is increased when the fingers are closed over a round hard object, as a crystal globe. It is also brought on or increased by such motions as reaching a book from a library shelf and particularly in putting on a coat. After such movements, the arm may feel weak and useless for a considerable time. Sometimes, there may be a suggestion of slight thickening felt over the external epicondyle; but this is never marked. Crepitus or abnormal mobility of the epicondyle is never noted.

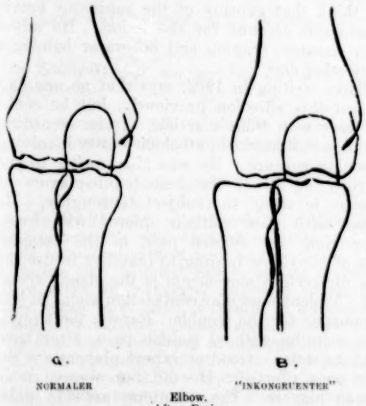
After a period of weeks or months, with or without treatment, the pain and the tender spot gradually disappear. The patient may again take up the favorite sport, with, however, a possibility of a speedy recurrence of the trouble. A considerable disability and discomfort may result from the injury,—much more than that only necessitating giving up the chosen exercise. Exactly the same trouble occurs from hard manual labor, as will be seen later.

From such a definite localization of the pain and tenderness with other suggestive symptoms of this injury, we may justly presuppose some characteristic and constant lesion of the tissues immediately adjoining the external condyle of the humerus. Tears of the fascia or some muscular bundle have been suspected in a general way, as well as nerve implication. Whatever the lesion is, it seems generally limited to that part of the external epicondyle affording attachment to the supinator brevis, extensor communis, extensor minimi digiti and anconeus muscles. Besides this particular region the humero-radial part of the joint capsule to which some of these muscles are attached has been suspected. Regarding the mechanism of the injury, it seems probable that it occurs during partial extension of the whole arm, the elbow slightly flexed at a time when the forearm is midway between pronation and supination, and that some of the muscles exerting a powerful pull, tear off their attachments to the external epicondyle, perhaps tearing off small pieces of bone with them. In cases where the exercise is repeatedly attempted after the initial injury, this process may be repeated in a lesser degree again and again; thus giving rise perhaps in some cases to a localized periostitis of the external epicondyle. This also may be kept up by the ordinary movements of the arm in daily life. It is established that simple rest of the elbow for a short time does not cure the condition. It may become quiescent and the patient might think it entirely cured, when the first stroke of his racket will bring back all the pain and disability. That numerous theories of the etiology of this condition have been put forth other than the above will be seen later. Certainly some of them do not seem to be compatible with the findings of the typical cases. Some authors even assert that the condition is noted without any traumatism at all and is the result of a bacterial infection at some time. It may be said that a careful examination of the cases seen gave no sign of a neuritis. The lesion is too sharply localized to be due to any involvement of the elbow joint as a whole. Exquisite tenderness on palpation of the epicondyle over a spot the size of a dime is pathognomonic of the trouble.

Brief anatomical considerations are now in order before taking up the various authors' views.

The external epicondyle, the radio-humeral part of the joint capsule and the supinator brevis muscle are the structures suspected of involvement by those who have made a study of this condition. According to Sobatta[4], "the centres of the epicondyle appear between ten and twelve years. But complete ossification of all parts of the bone and disappearance between synchrondroses between epiphyses and diaphyses do not occur until between the twentieth and twenty-second year. From the external epicondyle arise the superficial extensor muscles of the forearm. The external lateral ligament of the elbow, otherwise known as the radial, arises from the external epicondyle, and passes as to fassiculi to the annular ligament, with which a portion of its fibres are continuous. The humero-radial joint does not act as an independent joint. From a practical standpoint the elbow may be regarded as a hinged joint whose axis of movement passes through the two epicondyles. The humero-radial joint does not take part in this movement as the ends of the bones are hardly in contact in flexion. The humero-radial articulation is only passively involved in the pivot movement of the proximo radio ulna joint, since the radius rotates in the socket about its long axis, and the actual pivot movement takes place in the proximo and distal radio ulna articulation." According to McAllster[5], "the outer epicondyle is short and convex behind and its extremity inclines forward. Its upper part affords attachment to the extensor carpi radialis brevior. Below this from above downwards and backwards come the extensor digitorum communis, extensor minimi digiti, extensor carpi ulnaris, anconeus, and close to the supinator brevis the capsular ligament. The origin of the extensors of the hand area extends behind the capitellum as far as the outer lip of the trochlear." The supinator brevis, the muscle supposed to be most concerned in epicondylitis, or tennis-elbow, is a deep and short muscle under the above-named extensors. "It arises from the back of part of the epicondyle, external lateral ligament, orbicular ligament of radius and from a rough ridge on the ulna below the lesser sigmoid cavity. It is inserted in the outer third of the radius." If this muscle is injured in the movements of the arm which cause tennis-elbow, it is difficult to see how injury of the external lateral and orbicular liga-

ments and joint capsule can be avoided, they are so intimately connected. The orbicular ligament, moreover, is said to limit to some extent pronation and supination so that its injury in tennis-elbow would seem very probable.



Franke[5] named the affection epicondylitis. He speaks of its being due to injury in sports, particularly tennis, and also of its arising without trauma. He did not observe it in children but in men and women of the leisure class. He speaks of the classic pain with localized tenderness and believes that at times the process is due to a localizing of the inflammation due to the influenza bacillus. He cites his own case in this regard. He never saw it in those having gonorrhea, syphilis, diabetes, nephritis or tuberculosis. He is inclined to believe that a nerve disturbance of some sort and rheumatism may cause the trouble at times. He never noted pain in the radius or ulna in these cases. In two of them there were swelling of the skin over the epicondyle. Other pains and aches in the neighborhood of joints and bones were noted by him in some of his cases, especially the internal condyle of the femur, the tarsal and metatarsal bones.

Anti-rheumatics and Preissnitz compresses were used. Fixation of the elbow gave the best results. He chiseled off the epicondyle in some cases, but does not state the result of this procedure.

Bernhardt[6] considers that over-extension of the muscles attached to the external condyle is the cause of the trouble. He states that it has been named: "Epikondylagie" by Féré.

Momburg[7] reviews Franke's article and cites briefly 14 cases of what he terms periostitis from "epicondylitis humeri." Almost all his cases were in the laboring class and the injuries were contracted during manual labor in a number of cases. Lifting a heavy weight was given for the causes of some. The complaint in all his cases was the same:—pain in the elbow in the region of the external condyle so severe that work had to be stopped. This pain often extended from the epicondyle to the forearm and fingers; also at times to the upper arm and shoulder. (He is the only author who speaks of this.) Pronation, supination, flexion and extension of the hand and fingers, (not of the forearm,) was particularly painful. Objectively pain on pressure over the epicondyle was the symptom. No changes were noted in the skin over the epicondyle. Sometimes what seemed to be slight doughy swelling of the periosteum was detected. However, the Roentgen pictures show no bony changes. He can not agree with Franke that a nerve or rheumatic trouble is the cause of the pain and tenderness about the epicondyle. He believes it is a periostitis of the epicondyle, and that it is caused by muscular pull, and likens it to the periostitis of the tibia of soldiers, from constant marching. The trouble was seldom noted by him in the internal condyle, and he gives the reason as due to the different muscular attachments.

Preiser[8] refers to Franke's, Momburg's, Clado's and Bernhardt's articles and says he has seen the trouble many times. He thinks it gives a typical Roentgen picture and that this means a static trouble with the head of the radius. He shows by a diagram that in his cases the radial head is outside of a line drawn down as a continuation of the external epicondyle.

Elbow.
After Preiser.

The radial "inkongruenz" of Preiser.

Sketch A. Normal.

Sketch B. The radial head is outside of a line drawn down as a continuation of the epicondyle. This Preiser believes obtains in cases of "Tennis Elbow."

He thinks that the condition is predisposing to and often really signifies arthritis deformans cubiti. He believes that only in an elbow already deformed in the periostitic shadow visible. He does not consider the name "epicondylitis" or "periostitis" as appropriate; and instead proposes the term: "static deformity." His explanation of the trouble is as follows: that the supinator longus and supinator brevis muscles, at least the fibres of each that reach the anterior joint capsule, are antagonistic at the moment of simultaneous contraction of both muscles. Said simultaneous contraction of both muscles occurs only in one movement, when the hand is snapped strongly and quickly from volar flexion into strong adduction.

He finds, moreover, that the radio-humeral joint capsule is always very tender to pressure. No sign of periostitis is shown in these cases. He does not think influenza infection has caused the trouble. He says he had two cases in tennis-players. The onset of the pain in both cases was sudden. The pain was localized in the external condyle region and there was slight swelling. Perfect extension was possible in these cases, ruling out bony blocking of the joint by any gross fragment. The Roentgen picture showed normal bones in both cases. There was a collection of fluid at the side of the capsule

and he believed the lesion to be a humero-radial joint capsule tear, with chronic capsular inflammation. He cites the case of a smith who had exactly the same lesion as the two tennis players. This man was obliged to strike an iron kettle in a certain way while soldering it. He was obliged to have his hand round his body midway between pronation and supination with the elbow flexed and the whole arm adducted. Preiser does not think that rupture of the supinator brevis muscle can account for the lesion. He advocates massage, friction and hot-water bandages every other day.

Clado, writing in 1902, says that no one had studied this affection previously, but he could not have seen Bähr's article. It is, according to him, a well marked pathologic entity involving muscular rupture. He was able, owing to the courtesy of 12 of the best tennis-players of France, to study the subject thoroughly. He agrees with those authors quoted who wrote after him, that sudden pain in the external part of the elbow leading to inability to use the arm for certain movements is the classic symptom. Violent muscular contraction seems to him responsible for the trouble. Rarely, the trouble may come on without sudden pain, after hard play, he states. Good or expert players are the only ones affected. He did not observe it in women players. The symptoms are (1) pain, (2) "impotence functionel," (3) swelling, (not always noted.) The arm may fall as if paralyzed and the player can not continue playing. Other cases less severe were noted by him as well as by others, but the pain came on again at the first attempt to play. This pain was localized to the external epicondyle in the region of the supinator brevis. There was exquisite pain on pressure of the examining finger. There was no constant swelling in his case, and the skin was always intact. Passive movements of the forearm were not painful. Causing the supinator brevis to act immediately produced great pain. The movements of the elbow joint in flexion and extension were perfect; and gave no pain. Clado does not think that the external lateral ligament and synovial membrane can enter into the trouble from the nature of the symptoms; but the rupture and tears of the supinator brevis muscle account for all the symptoms. He admits that there is not enough swelling for total rupture of the muscle to have occurred. He never found a hernia of the muscle and ecchymosis was noted only once. To give a stroke which causes tennis-elbow, Clado says, the arm is transformed into a rigid lever, nearly horizontal, the elbow slightly flexed, the forearm and hand being midway between pronation and supination, the radial border directed upward, the racket prolonging this lever. He thinks the slight flexion of the elbow is maintained in this position by balance between the flexors and extensors; and the short supinator enters alone into action against the strong pronators and alone maintains the arm in equilibrium against its antagonizing muscles. He says that, in America, the expert players have a different style of game and that the muscles of the abdominal wall are torn and that one does not see tennis-arm in America. This, we know, is not so, if tennis-elbow and tennis-arm are used synonymously.

CONSIDERATION OF PERSONAL CASES.

I have had opportunity to study three cases of tennis-elbow, all in athletic men. None of them ever had had any previous trouble with his elbow.

CASE 1. On Oct. 16, 1913, while riding in an automobile, the right elbow was struck by a jolting of the car, but did not give any trouble until a week later, when, after playing lawn tennis, it felt somewhat stiff. On the following day, after half an hour's hard play, a sharp pain was felt in the outer side of the elbow and forearm on making back hand strokes, which require a fixed position of the arm half way between pronation and supination, and almost complete inability to make such strokes. At the same time, forehand strokes, requiring simple flexion only, were made with very little discomfort. On examination, an exquisitely painful point was found on the epicondyle. Otherwise the joint seemed normal.

Heat and rest seemed to make little change in the condition. The arm felt weak at times, especially after grasping any object firmly and lifting it or in putting on a coat. Disability has continued for three months and at present the patient is still unable to use the arm for exercise. Examination shows no atrophy; the radius rotates perfectly; no thickening is detected over the epicondyle. There is still marked pain on pressure over the epicondyle; the x-ray shows no gross bony abnormality. There is a question of a very slight thickening of the periosteum over the epicondyle. The radiograph, though fairly good, was not perfect enough to make this diagnosis positively.

CASE 2. Vigorous athletic man, seven years ago, after constantly playing tennis, noted gradually increasing pain in the right epicondyle. There was local tenderness in the spot complained of by all these patients. There was six month's disability. Examination seven years after this time, still showed tenderness over the epicondyle but no other abnormality. This patient was much inconvenienced by the trouble and played at squash rackets with his left hand at this time for six months. The x-ray in this case showed two little spicules of bone torn off presumably from the inner posterior surface of the condyle or epicondyle. An x-ray of the left arm, which had been used constantly at the time of disability, showed also a small spicule of bone apparently torn off from the internal condyle.

CASE 3. Athletic man, played squash rackets, tennis and golf. While playing golf, July, 1913, the patient noticed immediate pain in the right elbow just after a stroke. Patient was left-handed. The pain was not severe enough to make the patient drop his club, but there was a distinct sensation of something tearing in the neighborhood of the external epicondyle of the right arm. The injury was not severe enough to cause the patient to stop play that summer. An exquisitely painful spot

appeared over the external epicondyle. Flexion and extension of the fingers caused marked pain in this spot. There was considerable pain and disability for six months and the arm is not well at the present time of writing, January, 1914. There is aching at times over the region of the external condyle; considerable discomfort when carrying a bag or putting on a coat is experienced. Flexion and extension of the forearm is performed fully; but forced extension causes considerable pain in the region of the external epicondyle. An x-ray of this case showed what seemed to be a small spicule of bone in the neighborhood of the joint surface between the ulna and the humerus.

TREATMENT.

Patients with this trouble are naturally most interested in what steps can be taken to cut short their disability, and it must be admitted that treatment of the condition is very unsatisfactory. Most authors who have written on this subject agree that heat and fixation seem to be the best methods with massage as a supplementary measure. It is an affection which seems to be particularly stubborn and often takes its own time to get well in spite of any treatment; six months of disability or at least of foregoing the chosen exercise must be looked for in most cases.

CONCLUSIONS.

It would seem from a study of the trouble based on those cases in the literature and of the personal ones that there might be perfectly well two lesions causing the symptom complex known as tennis-elbow or epicondylitis.

First, a partial tearing of some of the muscular attachments from the external epicondyle, giving rise to the separation of the bony spicules as in Cases 2 and 3, with the possibility of a periostitis from such tearing, which need not necessarily be marked enough to show in a radiograph.

Second: Injury to the radio-humeral joint capsule from antagonistic muscular contraction of the supinator brevis and supinator longus, as believed by Preiser. It does not seem as if Preiser's theory of predisposition to arthritis deformans of the radial head could be accepted in all cases.

I thank Dr. W. E. Faulkner and Dr. John W. Cummin for valuable suggestions in the preparation of this paper.

RECENT ADVANCES IN THE TREATMENT OF SYPHILITIC DISEASE OF THE NERVOUS SYSTEM.*

DISCUSSION.

Dr. G. O. Sanborn: As discussion of these excellent papers, my own experience in the use of Swift's intradural method may be of interest. At the Boston City Hospital and in private practice, I have given 92 intradural injections of salvarsanized serum to 31 cases of syphilis of the central nervous system during the last eleven months.

The final test of efficiency of antisyphilitic treatment is the permanent disappearance of a positive Wassermann reaction. In syphilis of the central nervous system, pleocytosin, and globulin, both of them signs of syphilitic irritation, also must give way to normal conditions. It has been shown tonight that repeated doses of salvarsan intravenously produce improvement in these objective signs of syphilis of the nervous system. Nevertheless, this method, alone, has seemed to be inadequate and the reason appears to be that the blood borne salvarsan does not reach the spinal fluid or the chronic, walled off lesions in relation to it, in sufficient concentration to be spirochaeticidal. Swift's method is calculated to supply this need, in that salvarsan charged serum is injected within the dura and thus directly fortifies the spinal fluid. He showed that the serum injected is spirochaeticidal; that immediate improvement in pathologic conditions of the spinal fluid is due to the serum injected and not in great measure due to the salvarsan given intravenously; that clinical improvement accompanies serologic changes; that improvement may be lasting. The conception and development of this method is a notable scientific achievement.

I have studied the effect of this method in producing changes in the pathologic conditions of the spinal fluid in tabes, paresis, and in some other types of chronic nerve syphilis. The clinical course of these cases has been followed closely by Dr. Coriat. I will mention only these cases in which the diagnosis is clear clinically, and whose spinal fluids gave consistent abnormal findings, pleocytosis, positive globulin and positive Wassermann tests.

The technic is essentially that demonstrated to me by Dr. Swift at the Rockefeller Hospital, in November, 1912. In these cases, maximum doses of neo-salvarsan have been used. In one case having

* See pp. 441 and 452.

had 8 doses, the interval between was 8 to 10 days; in others the interval has been two or three weeks to three months. All have received treatment in a hospital, and have remained in bed at least 24 hours. There have been no deaths and no serious results of any kind. The reaction during the 24 hours after injection, in the tabetics, has consisted of pain, sometimes severe. Slight temperature also has occurred in a few cases.

The tabetics have received from 2 to 6 injections of serum. In none of these has a positive Wassermann become negative (1 c.c. of spinal fluid used). Positive globulin has become negative in two cases. The cell count has been affected strikingly by treatment. The average cell count in 11 cases before treatment, was 56. In the same cases, two weeks to two months later, with no intervening treatment, the cell count was 18, a diminution of 70% from one combined treatment. Ten of these cases, after 3 to 5 serum injections, each, gave a final average cell count of 9. The average of the total drop in cell count was 84%. Clinical improvement has been noted in all cases, as follows: general condition; gain of weight; all but two, less ataxic; pains ceased save in three cases, and in the latter are no longer severe; three had lost control of bladder sphincter, and have regained it. In three undoubted cases of paresis, cell counts of 100, 60 and 40, respectively, have dropped to normal, after 4 to 6 intradural injections. There has been definite and maintained clinical improvement in all. It is my intention to continue treatment of this group of cases until normal spinal fluids have been attained, or until I am convinced that this is impossible.

DR. A. MYERSON: My experience with Swift-Ellis treatment has been mostly limited to its use in general paresis. I have had two cases of cerebral spinal syphilis, both of which did very well treated by salvarsanized serum. I have treated eight cases of paresis for periods varying from three to seven months. Injections were given every two weeks in the majority of cases and the procedure was essentially as that advised by Swift-Ellis. As the results have been tabulated elsewhere (BOSTON MEDICAL AND SURGICAL JOURNAL), I shall not trouble you with a detailed report. Suffice to say that the most striking change was in the biological reactions. In the majority of cases, the Wassermann reaction was for at least a short time, negative in blood or spinal fluid, or both. The cellular count diminished and the globulin reaction became less intense. In none of the cases was this a permanent result, although in some, the biological improvement lasted for months. One case died, one other became markedly worse, these changes being in no wise related to the treatment since the patients were not selected from any stage of the disease. Clinically, change for better was not so obvious as serologically. One man had a complete remission, but as he was on the road to this before treatment commenced, credit cannot be taken by the treatment for this. Three of the patients remained stationary, two of the cases made some clinical improvement.

As for the rationale of the treatment, I believe that the change is based on a fallacy which does not affect its use and value in cerebral syphilis and tabes, but which in a case of paresis is fatal to the success of the treatment. The treatment presupposes a local effect of the salvarsanized serum, but I wish to point out that the cerebral spinal fluid does not reach the lesions of paresis except those in the meninges. The cerebral spinal fluid is not a route on the way *towards* the nervous system, it is a route on the way *from* the nervous system. It is not an *afferent* current, it is an *efferent* current. That is to say, no matter where it is manufactured, whether in the choroid plexus or by the blood vessels, whether it is transudate, exudate, dialyzed fluid or true secretion it does not enter into intimate relations with the nerve cells, nor does any fluid injected into it reach the nerve cell or touch the paper tissues of the nervous system. The lesion of general paresis is essentially arterial, chronic inflammatory and degenerate, and the bulk of the change takes place away from the influence of the cerebral spinal fluid; moreover, the spirochaetes have not been found superficially, but deep in the tissues of the brain, so that there seems to be no rational basis for the belief that the Swift-Ellis treatment, which has for its new feature the use of salvarsanized serum, will cure paresis.

Moreover paresis is a disease essentially characterized by remission. This is true of the biology of syphilis in general, and the state hospitals can present numerous cases where individuals have enjoyed such remissions from the effects of paresis as to enable them to go home, in some cases for long periods of time; further, no one knows the biological variations in paresis because no one has performed repeated lumbar punctures and serological examinations up to the time this treatment may be necessary.

In two of my cases, the Wassermann was negative the first examination, but positive at a later one without treatment and without any change in the clinical symptoms, and the reverse has been true in one case.

Reliance upon the cell counts as a quantitative measure is based, it seems to me, upon the belief that the counting chamber method can be accurate. I do not believe that such is the case. I believe the range of error to be as much as ten or fifteen cells per cubic millimeter in any case where there is a distinct cell increase. The most that one can really say in any case is that there is a small cell increase, a large cell increase, or very large increase, and approximate the figures rather than give them with a pretence of exactness.

Dr. Ayer has well called our attention to the fact that there is a preparetic stage, in which treatment is hopeful. With this I cordially agree and, moreover, I believe that this is a recognizable stage. In the period before the outbreak of paresis, there are symptoms. In this connection I want to call your attention to a paper by Dr. Wm. W. Graves of St. Louis which appeared on August, 1912, in the *New York Medical Report*. The title of this paper was "Syphilitic Syndrome," and Graves here points out that the chronic or latent syphilitic has physical signs of a nature to have a diagnosis made. These are pigmentation, pallor, small changes in the pupils, small changes in the reflexes, such as the dropping out of one or the other of the skin reflexes, exaggeration, inequality and arterio changes. To this I wish to add that on the laboratory side we can obtain evidence. First, the Wassermann reaction of the blood on repeated examination; second, the chemical changes in the spinal fluid, and especially of the increase in albumen, which I believe occurs before globulin reaction or the increased cell count of the Wassermann reaction. Taken at this stage, I feel we could cope, perhaps successfully,

with the disease, and perhaps by the Swift-Ellis method; but at the present time, and in the average paretic, treatment by this method influences the course of disease but does not stay it.

Dr. Isador H. Coriat: Dr. Sanborn and I have been closely associated in this combined neurological and serological work, and we have treated in all about 30 cases by the intraspinous method. The types of syphilitic diseases of the central nervous system which have come under treatment have been combined system disease of the spinal cord, specific meningo myelitis, cerebral syphilis, cerebrospinal syphilis, dementia paralytica, tabes and juvenile paresis. No bad results have followed the treatment. In nearly all cases there was serological improvement even if the cases showed no changes clinically. The clinical improvement could be grouped under two headings, viz:—improvement in the subjective complaints and improvements in the objective signs of the disease. As would naturally be the case, the subjective improvement was always more marked than the objective, although the latter was noted to a certain extent in a few cases. Varying according to the diagnosis, the subjective improvement was as follows: In tabes, a lessening of the lightening pains and of the gastric crises and an improvement in general strength; in cerebral syphilis, a diminution of the headache and even in some cases a complete freedom from headache; in spinal syphilis, increased strength in the legs and in paresis, some improvement in the mental condition. Of course in this latter disease, the question of fluctuation in the disease process and of remissions must be considered. Objective improvement has likewise been noted in a few cases, but in these cases only certain isolated objective signs have improved. In specific meningo myelitis, the gait has improved; in tabes, improvement of the urinary incontinence, of gait and ataxia, and improvement in certain reflexes, such as the light reaction of the pupils. In one case the knee jerks became brisk, whereas formerly they were only obtained on reinforcement. The significance of these changes in the reflexes, it is impossible to determine at present. The clinical improvement usually ran parallel with the serological improvement, although we have noted serological relapses without clinical relapses, and vice versa. The problem of treatment of syphilis of the nervous system is the problem of accessibility of the spirochetae. In specific endarteritis, of course, beneficial results are to be expected from intravenous injections of salvarsan. But in the meningeal forms, in paresis, tabes and system diseases where the causative agent lies at a distance from the blood vessels in the perivascular and perineuronal spaces, the best results are to be obtained by the intraspinous method of treatment, thus bringing both the drug and the syphilitic anti-bodies into direct communication with spirochetae. Since the cerebrospinal fluid does not come from the blood current, but is a true secretion from the choroid plexus and the direction of flow is from the fluid to the blood, it follows that the best treatment for syphilis of the nervous system is by introduction of the causative agent directly into the cerbrospinal fluid.

Dr. J. C. Walker: I am in sympathy with the remarks made by Dr. Coriat in regard to the cell count in the spinal fluid, and I do not agree with what I understood Doctor Myerson to state, namely, that the cell count in the spinal fluid varies from day to day, and is not to be depended on as an index of active disease of the meninges. At the Peter Bent Brigham Hospital we perform lumbar puncture on every case of syphilis and in forty or fifty cases in various stages, excepting cases of central nervous system syphilis, the highest spinal fluid cell count has been four, usually two and often none or one.

In regard to the Wassermann reaction, I believe that when done by an intelligent person who understands the reaction, and when conscientiously and carefully controlled, it is more than a symptom, and it is indispensable in the diagnosis of syphilis.

It is too late in the evening to enumerate the cases of syphilis which we have treated intraspinally, but our results agree with those of Doctors Ayer, Sanborn, and others, and I feel that this new method introduced by Swift and Ellis, is of great value as a treatment, especially in cerebro-spinal syphilis and of help in tabes. I would like to mention one case of cerebral syphilis with primary optic atrophy, which was given four intraspinal treatments alone without intravenous salvarsan treatments. This salvarsanized serum introduced into the spinal canal had no injurious effects upon the optic nerve, in fact before treatment there was a steady gradual decline in his sight. Since the treatment, although the patient thinks it has improved his sight very slightly, his sight surely has gotten no worse, and the decrease of the spinal cell count from forty-three to seven indicates improvement. A second case of tabes got no improvement from six salvarsan treatments alone, but four intravenous salvarsan and intraspinal treatments relieved his incontinence of urine, and whereas previously the patient had to get up four or five times at night to urinate, now he has to get up only once. In this case the pains in the lower extremities have disappeared, the gait has improved so much that the patient walks much daily for exercise, and the cell count has dropped from forty-four to two.

Book Reviews.

The Midwife in England. Being a Study of the Working of the English Midwives Act of 1902. By Caroline Conant Van Blarcom, executive secretary. New York: Committee for the Prevention of Blindness (No. 13). December, 1913.

This very readable pamphlet begins with an enthusiastic introduction by Prof. Edgar, who endorses all that the author has written. The aim of the writer is evidently to convince the general public of the necessity of the trained, licensed, and regulated midwife in America, basing her arguments on the success of the operation of the English Midwives Act of 1902. She was in England only six weeks observing midwives in the making at their recitations, lectures, and examinations; she followed the midwife on her rounds in practice, and she followed the inspectors in their work of checking up. She gives an accurate account of the history of the midwife in England down to the passage of the Midwives' Bill of 1902, and also a minute description of this bill and its operative machinery. The work concludes with four exhaustive appendices, making it a valuable book of reference.

THE BOSTON
Medical and Surgical Journal

THURSDAY, MARCH 26, 1914.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States. $6.56 per year for all foreign countries belonging to the Postal Union.*

Papers for publication, and all other communications for the Editorial Department, should be sent to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston. All orders for reprints must be sent in writing to the Editor on or before the day of publication.

The Journal will furnish 100 reprints free, if requested in writing.

All letters containing business communications, or referring to the publication, subscription or advertising department of the Journal, should be addressed to the undersigned

Remittances should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

THE HARVARD MEDICAL SCHOOL OF CHINA.

A CIRCULAR letter of information and appeal (reprinted in another column of this issue of the JOURNAL) has recently been sent by Dr. Martin R. Edwards to all graduates of the Harvard Medical School relative to the present status and needs of the Harvard Medical School of China. This school was founded at Shanghai in 1909 and inaugurated two years later.

THE HARVARD MEDICAL SCHOOL OF CHINA.

"The inauguration of the Harvard Medical School of China occurred precisely at the moment of the outbreak of the Revolution of 1911; but this, instead of hindering the development of the School, worked to its advantage. Along with the remarkable readjustment of government, there was a widespread awakening on the part of the Chinese to the necessity of a hygienic regeneration, if China is to take her rightful place among the nations. This realization, however, had really begun during the fight against the recent outbreak of pneumonic plague in Manchuria, which marked a new era in medicine throughout China's four hundred millions of people.

"The point of location, at Shanghai, offers exceptional opportunities for extended researches into the diseases of the Orient and the tropics. This is of importance to us due to the rapidly increasing intercourse, commercial and otherwise, of the United States with the peoples of the Orient and tropical countries. The approaching opening of the Panama Canal emphasizes this need.

"The course of study at the Harvard Medical School of China covers a five-year period, the teaching all being done in English. Although the school is primarily for Chinese, it is open to all who meet the entrance requirements. It is the aim of the school to give a high class of instruction to a limited number of well-qualified students who give promise of becoming leaders in China's medical advance, rather than to turn out large numbers of moderately trained doctors.

"The above buildings are furnished to the Harvard Medical School, free of rent, by the Chinese Red Cross Society. The larger building now provides facilities for the hospital, the lecture and laboratory rooms for instruction purposes, and the laboratories for research. The whole of this building, however, is needed for purposes of instruction and research, and will be so used upon the completion of the much-needed new hospital. The smaller building is used as a dormitory. The grounds afford ample space for tennis and other sports enjoyed by the students.

"The purchase of a tract of land near the school building on which to erect the new hospital is of vital importance. The money for the hospital building has already been promised. The carrying on of satisfactory instruction work for the students further demands the immediate establishment of an out-patient department in the heart of the city.

"The school has before it exceptional opportunities for usefulness; and, in the words of President Eliot, 'is one of undoubted worthiness and sure fruitfulness.'"

The need for trained physicians in China is great. The country has a population of 400,000,000, with only 650 doctors having a knowledge of modern scientific medicine. At this rate there would be but one physician in Boston and three in Chicago. Yet physicians are needed in China, for there is a large amount of endemic and epidemic disease.

"The Harvard Medical School of China aims to meet this need, to train carefully selected Chinese students of medicine, so that they later may

become the teachers, in native institutions, where the vast number of Chinese practitioners needed may receive their training. The aim is to help the Chinese to solve their own medical problem."

There is also a great need for hospitals in China. There are at present 250 hospitals averaging 30 beds each in that country. At this rate, Boston would have one hospital of 12 beds and New York one of 90 beds. The Harvard Medical School Hospital, soon to be built at Shanghai, is not solely an attempt to contribute towards meeting this need, but a means for providing more adequate opportunity for clinical instruction under favorable conditions.

The need of this hospital, both from the humanitarian and from the educational standpoint, is obvious. It is earnestly to be hoped that not only graduates of the Harvard Medical School, but physicians and patrons of medicine generally, may generously give the means to make possible this enlargement of the work and service of the institution in the Orient.

THE MIDWIFE IN ENGLAND AND IN AMERICA.

In another column of this issue of the Journal is published a review of a pamphlet which has recently come to hand. Its title is "The Midwife in England"; its object is the midwife in and for America. It is important to consider briefly the motive behind these written pages.

Miss Van Blarcom, the secretary of the Committee for the Prevention of Blindness, is a well-trained obstetric nurse; no one could be more familiar with this side of obstetric work than she. She was sent to England to investigate the midwife situation in that country; her time for study was but six weeks. There can be no doubt that she did her work thoroughly and well. She became in spirit an English midwife and writes with the loyalty of a proselyte. She honestly feels that the one and only solution of the obstetrical situation in America is some such system as England has adopted. She considers no alternative and bravely sweeps away all the barriers. We cannot but admire her enthusiasm and pardon her inconsistencies; but it is hard to see how obstetricians of wide training and influence can advocate her plans for America.

In the first place, the English system is far from being the unqualified success she would have us believe. In a lecture on "Ante-Natal Hygiene," by Dr. Armand Routh, consulting obstetric physician to Charing Cross Hospital, given on behalf of the National Association for the Prevention of Infant Mortality on January 13, 1914, one of the first principles advocated is for "arrangements by which every poor woman shall have medical supervision during pregnancy." In this long and exhaustive paper there is no mention made of even the most highly trained midwife as a factor in his plans for obstetric care of the poor; it is always the medical practitioner who is to give the service. The obstetricians in England know that the system they originally advocated, when they backed the Midwife Bill, is wrong, and that it cannot furnish adequate care for the poor of England in their obstetric experiences.

The crying need in America is not for trained midwives, but for higher standards of obstetric teaching in our medical schools and for the widespread introduction of obstetric dispensaries. A recent newspaper article written, not by a superficial reformer, nor by a biased obstetric specialist, but by a public health expert, Dr. W. A. Evans, of Chicago, concludes:

"It does no good to abuse midwives or poor doctors or poor nurses. It does no good to try to legislate midwives into trained women, or, following the other trend, to legislate them out of existence. The latter plan has not succeeded anywhere in this country, and the former plan has not succeeded anywhere in Europe. The reason is plain to anyone who gives it thought. I will not develop it.

"No plan ever will succeed except one of substitution. The thing substituted must not only save the eyes and the lives, but it must conform to other requirements.

"The lying-in hospital, dispensary, and mothers' aid movement constitute the best substitute to date. As a preventive of blindness, it is perfect. As a saver of lives of mothers and babies, it is almost perfect."

MEDICAL LEGISLATION. STATE REGISTRATION IN MEDICINE.

On Thursday, March 5, a hearing was held at the State House before the committee on public health relative to the proposed bill providing for the registration of physicians in this Commonwealth. The principal contention was made by the Christian Scientists. The proposed

bill contains ten sections, the ninth of which read originally as follows:

"Nothing in this act shall be held to restrict the practice of Christian Scientists, so called, who are communicants in good and regular standing in any Christian Science church in this Commonwealth, or to registered pharmacists or registered dentists, or to clairvoyants, or to persons practising hypnotism, mind cure or massage, provided they do not violate any of the preceding provisions of this act."

To the last clause of this paragraph the Christian Scientists objected, claiming that it in effect nullified all the rest of the section. After some conference between their representatives and those of the State Board of Registration in Medicine, the latter agreed to substitute for this section the following:

"Nothing in this act shall be held to apply to registered pharmacists, registered dentists, or registered optometrists, or to restrain the practice of clairvoyance, hypnotism or mind cure, or to apply to any person who ministers to or treats the sick or suffering by mental or spiritual means without the use of drugs or material remedy."

Upon this compromise, the Scientists withdrew their objections, and the latter section was therefore substituted as an amendment to the bill.

The last section of the bill is also of importance as defining the practise of medicine.

"Section 10. The word medicine, as used in this act, shall be regarded as referring only to that branch of science which relates to the prevention, cure or alleviation of the diseases of the human body, and any person shall be regarded as practising medicine within the meaning of section 8 of this chapter who shall publicly assume or advertise any title or designation which shall show or tend to show that the person publicly assuming or advertising the same is a practitioner of medicine in one or more of its branches; or who shall investigate or diagnosticate physical ailments, defects or conditions of any person, with a view to treat or modify the same, or does treat or modify the same, by use of instruments or external appliances or manipulations, or by the application or administration of any remedial agent or substance for either internal or external effect, except in so far as the provisions of this section do not conflict with the provisions of exemption in section nine."

Hitherto there has been no statutory definition of the practise of medicine, and the term has been variously interpreted by different judges. This new definition, it is said, will be of value to the courts as an aid in the adjudication of certain medical cases.

MEDICAL EXAMINERS FOR GREATER NEW YORK.

THE bill recently introduced into the New York Legislature abolishing the office of coroner in New York City and substituting for it that of medical examiner is a reform measure deserving of a most widespread interest. It is now nearly forty years since the General Court of Massachusetts without a dissenting voice voted to abolish the coroner system and to substitute for it the method of medico-legal inquiry at present operative in this Commonwealth.

The office of coroner, an ancient English institution, in these days is an anachronism. Notwithstanding this fact, in but a few states of the Union has it been replaced by other systems of medico-legal inquiry. Massachusetts, the pioneer, has been followed by Rhode Island, and in a measure by Connecticut, New Hampshire and Maine. New York now seeks to follow suit, and in so far as the City of Greater New York is concerned to rid herself of the antiquated, cumbersome and in a measure corrupt method of inquiry which up to the present time has persisted in spite of all effort to abolish it.

The people of Massachusetts may well take pride in the fact that the promoters of the New York bill before drafting the measure made careful inquiry into the Massachusetts medical examiner system and its workings as exemplified in Suffolk County, where conditions are favorable to its most effective operation.

The friends of the bill include organizations representing a wide variety of interests united in vigorous effort to secure its passage. Should the bill become a law, New York will set a powerful example in the direction of a reform, the need of which in this country is universally conceded.

MEDICAL NOTES.

SYNTHETIC MILK.—A press report from London on March 17 announces the discovery there of a method of making synthetic milk from the soya bean.

A CENTENARIAN COUNTESS.—Elizabeth Ruth, Countess of Devon, who died at Cheltenham, England, on March 17, is said to have been born on March 12, 1814. She was widow of the tenth Earl of Devon.

The Plague in Java.—The total number of cases of bubonic plague notified in East Java during the calendar year 1913, was 11,218, with 10,556 fatalities.

Mississippi Valley Medical Society.—The twenty-sixth semi-annual meeting of the Mississippi Valley Medical Society was held at Lincoln, Neb., on March 26 and 27.

Insanity in Wars.—During the Franco-Prussian War, the percentage of insanity among troops engaged was 0.73 per 1000. During the British South African War it was 2.5; in the Russo-Japanese War 2., and in the recent Balkan War only 0.35.

A Long Retained Lithopedion.—In the issue of the Journal for Jan. 15 we quoted a case of a lithopedion retained in the abdomen for 42 years and during four succeeding pregnancies. In a letter published in the issue of the *Lancet* for Feb. 28, Dr. W. S. Lamb notes that there is in the Army Medical Museum, at Washington, D. C., a lithopedion removed at autopsy, which was retained in the abdomen 55 years and during five succeeding pregnancies.

BOSTON AND NEW ENGLAND.

New Evening Clinic at the Dispensary.—On March 16 a new evening genito-urinary clinic was opened at the Boston Dispensary. This clinic will be held on Monday, Wednesday, and Friday, at 7.30 p.m., and a fee of 50 cents will be required of each patient. The clinic will be in charge of Dr. Arthur H. Crosbie and Dr. Augustus Riley.

Scarlet Fever at Bridgewater.—It is announced by the local board of health that the epidemic of scarlet fever, recently prevalent in Bridgewater, Mass., is now abating. On March 13, there remained only 32 cases of the disease under treatment.

Hospital Bequests.—The will of the late Francis J. Cotting, of Boston, which was filed on March 18, contains bequests of $10,000 to the Children's Hospital, Boston, and $75,000 to the Industrial School for Crippled and Deformed Children.

By the death, on March 15, of Mrs. Abram H. Cushman, of Peabody, Mass., a trust fund of $40,000, of which she enjoyed the income, under the will of the late J. B. Thomas, now reverts to the J. B. Thomas Hospital.

The will of the late Laura Wolcott Lowndes, of Washington, D. C., which was filed in that city on March 14, contains a bequest of $10,000 to Harvard College to provide free beds for needy students in the Stillman Infirmary.

The will of the late Dr. Thomas Morgan Rotch, of Boston, after providing for the endowment of a professorship of pediatrics in the Harvard Medical School, makes the Infants' Hospital his sole ultimate reversionary legatee.

The will of the late Martha B. Webb, of Brookline, Mass., which was filed last week at the Norfolk probate court in Dedham, Mass., contains a provisional residuary bequest to the Beverly, (Mass.) Hospital.

Infectious Diseases.—Cases of Infectious diseases reported to the Boston Board of Health for the week ending March 17, 1914: Diphtheria, 59, of which 5 were non-residents; scarlatina, 144, of which 11 were non-residents; typhoid fever, 3; measles, 57, of which 1 was non-resident; tuberculosis, 42, of which 1 was non-resident.

The death-rate of the reported deaths for the week was 16.32.

NEW YORK.

Abolition of Coroner's Office.—On March 11 the Assembly Committee on Cities gave a hearing at Albany on the Brennan bill abolishing the office of coroner in New York City. Under this bill the bulk of the work now done by the coroners would be taken over by a chief medical examiner appointed by the mayor and a number of deputies appointed by the chief examiner, while the rest of the work would be performed by the city magistrates. Dr. George B. Magrath, medical examiner in Boston, explained the economical and satisfactory working of the medical examiner system in Massachusetts, and among those who appeared in favor of the bill were Dr. A. Jacobi and Prof. James Ewing of Cornell University Medical College.

Hospital Bequest.—By the will of the late Mrs. Elizabeth N. Andreas of Brooklyn, N. Y., $4,000 each is left to the Stony Wold Sanatorium for Incipient Tuberculosis, in the Adirondacks, St. Rose's Free Home for Incurable Cancer, New York, and the Seaside Home of the Brooklyn Children's Aid Society.

Manhattan State Hospital.—After several years of negotiations, an agreement has been

approved by the state and the city of New York giving to the state a lease of Ward's Island for fifty years for the Manhattan State Hospital for the Insane and transferring to the state the property in Brooklyn occupied by the Long Island State Hospital. The transactions were made possible through the enactment of two bills by the Legislature last year, upon the recommendation of the attorney general and the State Hospital Commission. The Manhattan hospital has been located for many years on Ward's Island without definite legal right, and during its occupancy the state has expended some $1,238,500 for improvement and repairs of existing buildings and the erection of new buildings.

NEW STATE HOSPITALS.—Among the recommendations in the annual report of the State Board of Charities is the establishment of two new institutions for the delinquent feebleminded, one for each sex, with observation stations in New York, Buffalo and other cities. Another recommendation is the establishment of at least three state hospitals for incipient tuberculosis, similar to the one at Raybrook, in the Adirondacks, together with increased hospital provision for the care of advanced cases of the disease.

REËNACTMENT OF WORKMEN'S COMPENSATION.—The constitutionality of the workmen's compensation act passed in December last having been questioned, the present legislature, at the request of Governor Glynn, reënacted it, with slight changes, and on March 16 the governor signed the bill and appointed four of the five commissioners whose function it is to administer the law. One of these is Dr. Thomas Darlington, the former head of the New York City Health Department.

TRUTH AND ANTI-VIVISECTIONISTS.—The general public has long realized that many of the charges made by anti-vivisectionists against the medical profession are utterly silly. How much credence can be placed in their recent charges that children treated in hospitals of this city were inoculated with "loathsome diseases," even though such charges are apparently fully supported by a statement giving names and addresses of the children alleged to have been so infected, is well shown in some correspondence which Commissioner Goldwater has recently had with Dr. William H. Maxwell, City Superintendent of Schools. Not only were the children found not to be suffering from the "loathsome diseases," but it was also shown that there was absolutely no experimental work with such diseases carried on in any of these hospitals of the Department of Health.

The charge was also made that many of the children attending the public schools in the Bronx were suffering from venereal diseases and it was plainly intimated that these were due to experimentation and infection in city hospitals. In particular, B. S. Deutsch addressed a letter to the District Attorney of Bronx County, stating that forty-eight children residing in Bronx County, many of whom were now attending the public schools, were suffering from a very grave venereal disease, namely, syphilis. Mr. Deutsch's statement goes on to say that the alleged infections of these children were the result of "inoculation which occurs without the consent of either the children or their parents, or else as the result of gross negligence or carelessness within the hospitals."

Commissioner Goldwater's investigators visited forty families named in the Deutsch list. Of this number, fifteen could not be found at the given addresses. Interviews were obtained with twenty-five families in which there were thirty-four children. Among these, not a single case of syphilis or of suspected syphilis was found. There was no evidence of the inoculation of any of those children with serum or vaccine.

RESTRICTION OF CORROSIVE SUBLIMATE SALES.—Report from Albany states that on March 5 the Senate committee reported favorably the Blauvelt bill, which restricts the sale of corrosive sublimate tablets by providing that they shall be colored green, placed in a bottle of distinctive shape, and dispensed only on a physician's prescription.

ANOTHER CASE OF TYPHUS FEVER.—On March 9 a case of typhus fever was discovered aboard the French steamer *La Savoie*, which reached this port on the previous day from Havre. All her steerage passengers were detained at the quarantine station.

MENINGITIS FROM GREECE.—A number of cases of cerebro-spinal meningitis have recently been discovered among immigrants from Greece, and

among Greek soldiers returning to this city after serving in the Balkan War. The disease is endemic in Greece, and there is probably a considerable risk of its introduction as an epidemic into this country. The vigilance of quarantine officials should be doubly strict at this time to prevent such a catastrophe.

City Health Department.—The officials of the City Health Department have expressed themselves as much gratified by the cordial support promised the department by the present municipal administration at a recent meeting arranged by the Charity Organization to celebrate the 31st anniversary. Three of the speakers on that occasion were Mayor Mitchel, Comptroller Prendergast, and Mr. McAneny, president of the board of aldermen, and looking to the commissioner of health to bring the machinery of his department to the highest degree of efficiency, they pledged themselves to give the heartiest support in their power to all efforts to improve the health and welfare of the community. Some of the activities commended by them were: Health centres, organized public health education, improvement in hospital and dispensary conditions, better supervision of foods, broadening of the work of the infant milk stations, and better supervision of and increased accommodations for the care of the tuberculous.

Treatment of Venereal Diseases.—The Health Department believes that Wassermann tests should be made upon all cases of syphilis, that there should be facilities for making microscopical examination for treponema, and that complement fixation tests and microscopical examinations for gonococci should be made in all cases of gonorrheal infection prior to discharging the patient. It has published a list of college, hospital and dispensary clinics which have taken special pains to come up to this standard, and expresses the hope that the example set by these will soon be followed by other clinics, and that in the near future the clinic treatment of the venereal diseases will be on a thoroughly scientific and satisfactory basis.

Medical Economic Leagues.—The Federation of Medical Economic Leagues, the object of which is the furtherance of the economic interests of the profession, and in which there are now seven organizations, with a membership of 2800, was incorporated at Albany on March 6. The president is Dr. Thomas Dixon of Brooklyn, and among the other incorporators and directors are Drs. A. C. Geyser and Oscar Potter of the Borough of Manhattan and Drs. M. L. Volk and Samuel Gitlow of the Borough of the Bronx. The chief aim of the central organization at this time is stated to be to induce the Legislature to prohibit hospitals and dispensaries from exacting fees from charity patients.

Award of Nicolls Medal.—On March 6 the Chemists' Club of New York presented the Williams H. Nicolls medal to Dr. M. Gomberg, professor of organic chemistry in the University of Michigan awarded for his researches in triphenylmethyl. On the same occasion friends of the late Dr. Morris Loeb presented to the club a bronze bust of Professor Loeb.

8. Mahr, H. W. *A Special Burette for Use in the Rideal-Walker Test.*

2. Trimble reports two cases of primary lingual tuberculosis. In any case of tongue ulceration, he says, tuberculosis must be considered. Most tuberculous ulcers of this organ are secondary. The diagnosis of this condition is very difficult, as it is impossible to demonstrate the bacilli in the ulcer and histologic examination alone is practically useless as a means of distinguishing it from syphilis.

2. Eastman suggests the anastamosis of the caput coli with the upper rectum as a new method of short-circuiting the colon and getting certain and efficient drainage.

6. Kanavel is convinced that a toxemia other than bacterial is a factor in the mortality of extraperitoneal rupture of the duodenum. He refers to the well-known work of Maury and to two illustrative cases.

7. Verhoeff proves experimentally that ultraviolet light cannot under any conditions destroy bacteria within the cornea, even when the latter is perfectly transparent, without at the same time severely injuring the corneal tissue.

8. The authors have worked out a formula which involves body weight before and after transfusion, and hemoglobin per cent., whereby the exact amount of blood transfused can be measured. They claim it is always safe to take one-fourth of the donor's blood and often safe to take a third, provided the transfusion is not done too quickly. The patient's blood-weight is estimated as one-nineteenth of the body weight. [E. H. R.]

1. Stewart reports on a clinical study of the circulation in the hands in cases of heart disease. He finds that the hand flow is more apt to be markedly deficient where there is evidence of serious impairment of the myocardium with disturbance of force and rhythm, than in cases with gross valvular lesions where the heart action is strong and steady. This is true even when in valvular disease clinical signs of broken compensation are present. In aortic insufficiency the hand flow is less easily maintained at the normal level than in mitral insufficiency. Even where there is considerable venous engorgement in cardiac cases the flow in the hands may be little if at all diminished, provided the myocardium is not impaired, and a diminution of the flow in the course of such cases is often an indication of impending myocardial failure.

2. Bass and Wessler studied the blood-pressure in children, showing orthostatic albuminuria. They found that blood pressure in these cases varied very little from that of normal children.

4. Howell reports on a clinical study of the blood in hemophilia, thrombosis and purpura. In hemophilia, he says, the blood is deficient in prothrombin, and there is a relative excess of antithrombin. The detection of a hemophilic condition of the blood is facilitated by first oxalating the blood and then recalcifying with an optimum amount of calcium. Under these conditions the coagulation time of normal plasma is very constant (9 to 12 minutes), while that of hemophilic blood is greatly delayed. In spontaneous venous thrombosis there is evidence of a diminution in the antithrombin of the blood, with normal prothrombin. In purpura no evidence was found of any variation from normal in either the antithrombin or prothrombin.

5. Geyelin reports on a clinical study of amylase (diastase) in the urine. The amount of this enzyme in the twenty-four-hour specimen of a normal individual (estimated by the Wohlgemuth starch-iodine method) varies within very narrow limits, and for a given case is almost a constant factor. In the vast majority of cases of acute or chronic nephritis the diastatic value of the urine is subnormal or totally absent. In cases with marked albuminuria it may be normal, indicating that the presence of albumin increases enzyme activity. Allowance must always be made for this factor in estimating the diastatic value in nephritic urine. As a test for renal function in nephritis, this method gives results agreeing remarkably well with those of the phenolsulphonephthalein test.

7. Soper and Granat studied the urea-content of the spinal fluid and its diagnostic and prognostic

significance. They find that a urea content higher than 0.2% indicates a severe uremia and a rapidly fatal termination. A content between 0.1% and 0.2% means a rapidly fatal termination in the majority of cases of nephritis. A content between 0.05% and 0.1% suggests severe urea retention.

8. Thomas and Ivy made a careful clinical study of the gonococcus complement-fixation test. They believe that a positive reaction is invariably reliable and always denotes the presence of a focus of gonococcic infection. The reaction is often negative in acute and subacute urethritis, especially if the inflammation is limited to the anterior urethra. In chronic posterior urethritis, in epididymitis, and in arthritis the reaction is practically always positive; in stricture about two-thirds, in chronic prostatitis about one-half of the reactions are positive. In women reactions are negative unless the infection ascends to the level of the uterus. A positive reaction is present in about 20% of patients clinically cured. [L. D. C.]

12. *HUSSY, J. B. *Pulmonary Tuberculosis and Its Vicious Circles.*
13. DOUGLAS, A. *Further Notes on Mental Suggestion by Transference.*

1. Hunter believes that many of the anemias are due to a septic process going on somewhere in the body, producing poisons which cause the anemia. These, and their relationship to oral sepsis, he proceeds to discuss. Much of the paper dwells upon the author's own work, and the justification and importance of this. It is picturesquely written and presents many important points in a novel way, though presenting little that was not already known. He presents his conclusions in an elaborate and overcomplex table.

2. Guthrie and six others discuss the registration of syphilis and gonorrhea. With one exception they are agreed that such registration under conditions as they now exist in England will not produce any good results.

5. Rivière urges further use of physical agents in treating diabetes. Among others he considers hydro-, mechano- and electro-therapy. These should, of course, go along with the regular dietetic regime.

12. Hussy, in an interesting paper, presents and discusses many of the problems arising in the course of pulmonary tuberculosis as vicious circles. He points out how, for instance, social misery, poor housing, etc., gives rise to tuberculosis, which in turn causes more social misery; the disease causes a cough, which in turn spreads the disease; fever makes the patient chilly so that he stays indoors, which in turn is bad for the tuberculosis and causes more fever. Likewise in regard to emaciation, hemoptysis, dyspepsia, anemia, night sweats, neurasthenia, pleurisy, cardiac failure and others he points out how a vicious circle may be formed and then discusses how it may be broken. 2. Voelkel, according to Abderhalden's theory, made peptone-free extracts from diphtheria, anthrax, and typhoid bacilli, from certain trypanosomes and from the spirocheta pallida. He tested the serum of animals or patients infected with these organisms

against their extracts to discover the presence of specific proteolytic ferments.

The sera of animals and patients infected with typhoid were capable of splitting the typhoid bacillus albumin. Negative results were obtained in anthrax, diphtheria and trypanosomiasis. In a few syphilitic patients the serum split the albumin of the spirocheta pallida. In these cases the Wassermann reaction was strongly positive. Thus Voelkel concludes that in certain infections, the diseased serum has the power of forming peptone from an extract of the infecting agent.

11. In psychiatry, during recent years, considerable attention has been paid to the glands of internal secretion as having an influence on the symptoms encountered. Schmidt conducted the following investigations on 34 cases of dementia precox, and on 36 normal individuals or patients suffering from other psychoses. Blood-pressure determinations were made before, and at intervals after, the intramuscular injection of .4-.5 of a milligram of adrenalin. Schmidt found that the control cases reacted to this dose by a rise in blood-pressure of from 40-80 millimeters of mercury. None of the dementia precox patients showed an increase of more than 20 millimeters of blood-pressure, while the severer and acuter cases showed no change. Schmidt concludes that lack of susceptibility to adrenalin is a means of differential diagnosis between circulatory and catatonic stupors. He does not attempt to explain his findings. [R. F.]

3. Jacob reviews the literature on staphylococcus septicemia and reports eight cases of his own. Of these, three were due to primary osteomyelitis or paranephritic abscess, and ran a typical clinical course. The portal of entry in the other cases was unusual, arising from infected tonsils, from the intestinal canal, or from bronchiectatic cavities in the lung. Jacob reports this series to emphasize the importance of bacteriological investigation of blood and urine for the diagnosis and prognosis of all fevers of obscure origin. According to his observations, blood or urine cultures were positive in every instance, and the number of colonies which were recovered were in a general way parallel to the clinical severity of the disease.

5. It is recognized that various infections have seemed to be an etiological factor in diabetes mellitus. Welz reports two cases of erysipelas which developed typical diabetes a short while after recovery. One case came to autopsy and was found to have cirrhosis of the liver and degeneration of the islands of Langerhans in the pancreas.

In his discussion Welz admits that it is difficult to prove that the erysipelas was related definitely to the production of the diabetes. Nevertheless, he considers that the infection in his patients was the exogenous cause of the constitutional disease, according to Naunyn's theory that the majority of diabetics show a congenital defect in carbohydrate metabolism which leads to a true insufficiency upon the imposition of a variety of other factors. [R. F.]

BERLINER KLINISCHE WOCHENSCHRIFT.

8. BARTSCH. *Accidents in Sports.*
9. LISSAUER. *Experimental Cirrhosis of the Liver.*

3. The author reports a striking cure by this means, which has also been tried and reported by Mosetig-Moorhof, Nolen, Folet, and Schmidt and Meyer. The patient was a young man of 16, who in spite of two laparotomies with the evacuation of respectively 6 liters and 2 liters of ascitic fluid, and in spite also of hygienic treatment, was becoming consistently worse. There was marked thickening of the peritoneum and omentum, and stubborn ascites. Between March 6, 1913, and May 17, 1913, he had four injections of the nitrogen gas varying from 500 c.c. to 800 c.c. in amount. On Nov. 13, 1913, he presented himself as symptomatically cured, and feeling perfectly well. The physical examination was negative save that in one area the now slightly thickened omentum could be felt. The abdomen was soft. This case seems like an authentic cure, especially as the amelioration in the symptoms and signs began immediately after the first injection.

[R. H. M.]

No. 4. JANUARY 26, 1914.

1. *KÜTTNER. *Intestinal Colic—The So-called Umbilical Colic of Children (E. Moro).*

7. GHIRON. *The Kidney Function in Reflex Anuria.*
8. LISSAUER. *Experimental Cirrhosis of the Liver (Concluded).*

1. Moro of Heidelberg has described a condition of periodic recurrent colic in the region of the umbilicus, in children over four, which he calls "recurrent umbilical colic." The pain is sharp comes on very suddenly lasts only a few hours and may or may not be accompanied by vomiting. The pain is always confined to the region of the umbilicus. Moro says that these cases are usually entirely functional and due to a neuropathic disposition, though occasionally there is an objective finding, such as diastasis of the recti, or chronic obstipation. Küttner disputes these remarks, and reports six of these cases entirely cured by appendectomy. In his opinion Moro is wrong in saying that the condition is commonly a neurosis, and he claims that the majority of cases can be cured by removal of the appendix.

5. Arneth reports a case of pernicious anemia in a woman of 67 treated with thorium-x at frequent intervals for a period of a little over two months, with the following results: The red cells went from 1,904,000 to 3,064,000, the leucocytes from 1000 to 4200, and the hemoglobin from 42% to 70%. The subjective symptoms were improved. [R. H. M.]

Miscellany.

MEMORIALS.

THE Fellows of the Norfolk District of the Massachusetts Medical Society in the recent decease of our respected member, Roderick McLennan, M.D., adopted for record the following memorials:

RODERICK MCLENNAN, M.D.

Dr. Roderick McLennan came to Quincy in 1887, in his early manhood, gave to its people his entire professional life and was removed from their midst at the age of man's maturest judgment and safest and most valuable action.

Modest and retiring in manner, he was without fear in action, ever thoughtful and respectful of the welfare of the society and its members.

Never striving for external show, yet ever ready to advise and suggest where his wisdom and opinion were required. Never aspiring to public office, he was a valuable member of the medical and surgical staff of the Quincy City Hospital from its inception; also giving his valuable time and services to offices in our local society.

Of deep and broad training, with a store of wisdom and good judgment gleaned therefrom. Ever ready to give assistance to colleague and patient.

His presence will be missed at our meetings, at our hospital and in the sick room. His cordial salute, the hearty grasp of hand has gone, but the memory of the good physician will remain in the hearts of his colleagues whom he honored in life.

The members of the society extend to his bereaved family their heartfelt sympathy in their great affliction. To those to whom he gave unstintingly and unselfishly of his services as the good Samaritan, condolence is extended at this time.

Resolved, That this memorial be spread on the records of the society and a copy be sent to the bereaved family.

JOHN H. ASH, M.D.,
E. H. BUSHNELL, M.D.,
D. A. BRUCE, M.D.,
Committee on Resolutions.

At a meeting of the Norfolk South District Medical Society the following memorial was adopted:

JOHN FREDERICK WELSH, M.D.

Deeply sensible of its loss by the death of Dr. John Frederick Welch of Quincy, the Norfolk South District Medical Society desires to record the great respect and high esteem in which he was held.

Graduating in 1880 from Bellevue Hospital Medical College, his career is an example of a self-made man of the best type. Frank and outspoken in manner and ever loyal to his friends, he has always stood for honorable conduct and high ideals in the medical profession and in the community.

As a member of the society, for many years its secretary, and its president in 1905 and 1906, he has been active in its support, and his wise conservatism and good judgment have been invaluable. For more than a generation he has practised his profession with unceasing devotion, attaining a high reputation by his skill, and enlisting the love of his patients to a marked degree. Although no longer with us, his memory is an inspiration and his example forms a perpetual ideal for his associates.

JOHN A. GORDON, M.D.,
NATHANIEL S. HUNTING, M.D.,
OLIVER H. HOWE, M.D.,
Committee on Resolutions.

Correspondence.

RELATIVE TO THE REGISTRATION OF NURSES.

NATICK, MASS., March 17, 1914.

Mr. Editor: I have read with interest your editorials on House Bill 1186 in the JOURNAL for March 5 and 12, and would like to comment on two or three points:

1. The objection made by the opponents last year "that it would place too much power in the hands of the board."

2. "That similar training school inspection has proved of value and success in New York and Illinois, where it has already been adopted. Such examples are important arguments in its favor."

Last year's bill and also the one this year contain this provision: "Applicants for registration—must

have received a certificate of graduation from a training school—*considered reputable by the board.*" (Italics are mine.) These bills were submitted to persons who have accurate knowledge as to the results of inspection elsewhere, and decided exceptions were taken to the clause italicised. One reply says: "I should seriously object to this clause because it places too much power in the hands of any board with absolutely no limitations. It is just such a clause which has caused much trouble in Illinois."

Another, who has had experience as hospital superintendent writes:

"I think there ought to be a clause somewhere that prescribes just how far the investigation may go. It will not be conceded that investigators of training schools will have any powers of regulation of the hospital administration, or equipment or architecture, and unless there is something specific put in your law, and unless the registration officers are an exceedingly high class group of people, there is likely to come disagreements about the scope of this investigation. In the case of a nurse inspector who had impressed herself on the members of the board, the board would relegate its duties to her and this would be hazardous. It is a good deal easier to safeguard the situation in the law itself than to presume on the personal factor in the enforcement of the law. Obviously, legislation must be taken independent of the personal equation."

It is evident that the opposition has very good company

The argument that any abuse of power by the board could be rendered nugatory by changing the personnel of the board, since it is appointive, is really an admission that such opportunity for abuse of power does exist in the proposed law. Would it not seem the part of wisdom to safeguard by law any abuse of power rather than to depend on changing the membership of the board?

One would hardly expect New York and Illinois physicians and hospital superintendents would oppose and criticise a training school inspection that "has proved of value and success in New York and Illinois, where it has been adopted." What are the facts?

I quote from a paper entitled "Some Problems in Relation to Nurses' Training Schools," read at an annual meeting of the New York State Medical Society by Dr. Charles Stover, as follows:

"We may not inaptly call this the era of control by the New York State Nurses' Association. . . . One of the tendencies in the United States is to plan the course of instruction for the evolution of hospital administrators, ignoring the public demand for ordinary and domestic nurses. . . . Only ten per cent. of the nursing outside of the hospital is done by them." (Meaning graduate nurses.) "Is this the best return that the hospitals can give the public that supports them? What has the nurse organization done to meet the crying needs of the poor and middle classes for nursing at a moderate cost? . . . Why should not this society of 6,762 members have a voice in the evolution of a more ideal nurses' training school?"

At this meeting a committee was appointed, consisting of Drs. Stover, ex-president of the society, Egbert LeFevre, dean of the University and Bellevue Medical College, Alexander Lambert, professor in Cornell Medical College, and Roswell Park, of Buffalo, the famous surgeon. In its report the committee says: "It is a fair conclusion that the standard for entrance in New York is too high for practical results. . . . It is more important that the people have small hospitals than that a few highly trained nurses obtain the thus-far little coveted title of R.N. . . . Meanwhile your committee is of the opinion that the State should recognize the nurse problem as an experimental one, to be regulated at present by wise adminstration rather than by legislation."

In 1912 the Executive Committee of the Hospital Conference of the City of New York appointed a special Committee on the Training of Nurses to act with the President to secure either such modifications, or interpretations of the existing regulations "as shall render it possible for the hospitals of the city to continue the training of nurses in sufficient numbers to meet the demands for trained nursing service." This committee consisted of the superintendents of the Presbyterian, the Post-Graduate, the St. Luke's, the Roosevelt, the New York, the Methodist-Episcopal, the Bellevue and Allied, and the Mt. Sinai Hospitals. Space will not permit the report in full but it says, in part:

"The strict enforcement . . . governing the admission of probationers to registered training schools for nurses is impracticable. . . . It creates a dearth of pupils and hence of New York graduates. . . . We urge upon the Education Department such amendments as will give the authorities a freer hand in the selection of probationers."

It may properly be asked why do these physicians, and superintendents of hospitals representing 3000 beds, make such strong protests, if "the New York law is the best one in the United States"?

Emerson is reported to have said that "Justice is the fairest thing all around." The criticisms of the New York law would seem to show that it does not conform to Emerson's idea of justice.

The foregoing quotations are only a few of the many criticisms which I have, some of them personal letters, but these will suffice for now.

One might infer from your editorial of the 12th inst., that the State Board of Nurse Examiners is unanimous in its support of House Bill 1186, but that is not so. At the hearing, held on the 5th inst., one member of the board appeared in opposition.

All will agree that "The public needs protection against incompetent nurses as well as against incompetent physicians." But it is every year becoming more evident that registration of nurses protects only about one-tenth of the public, while the nine-tenths are left unprotected. It is self-evident that if any are entitled to legal protection those who are not able to pay the high fees of registered and trained nurses should receive at least equal consideration with those of abundant means. Today every state where nurses are registered virtually says to its inhabitants: "You who can pay the price can have the protection afforded by registration but you who can not pay the price must take your chances."

The time is nearing when "the public," which includes *all* the citizens, should demand legal protection against incompetency in any and all who nurse for hire, and this protection should embrace the poor as well as the rich.

In New York the standards which a training school must measure up to in order that its graduates may be allowed to take the examination for registration are so rigid that they debar the graduates of one of the best training schools in this state, yet those in authority acknowledge that the school in question gives an exceptionally fine training, and say to the school: "If you will promise to give two 'consecutive' years in the hospital instead of two years not necessarily consecutive, we will register your graduates, both past, present and future." This reminds one of John, the disciple, when he said to Jesus: "Teacher, we saw one casting out demons in thy name, and we forbade him, because he followed not us." Casting out demons, but not "following us." Training nurses successfully, but not "following us."

In the *Journal of the American Medical Association* for March 14 is a paper read at Chicago February 24, 1914, before the Tenth Annual Conference of the Council on Medical Education, by President Lowell of Harvard University on "The Danger to the Maintenance of High Standards from Excessive Formalism." President Lowell describes the present tendency in the training of nurses and the inspection of training schools so aptly that I quote at some length:

"My concern is the rules adopted at the joint meeting last March of the Association of American Colleges and the Council of the American Medical Association about the courses to be taken in college." . . . "We

are to ask not what a man knows, but whether the man has taken a course with a fixed number of lectures and laboratory work." . . . "You are using a rough mechanical test which is inaccurate on both sides, instead of a personal test which would be far more accurate." . . . "Americans are a mechanical people who trust to machinery to do their work, maintain standards and save labor. But mechanical devices as applied to human beings are apt to be defective, and in education they present, at the present time, a real danger. This runs from the top to the bottom of the educational scale." . . . "Our processes of education are inelastic, and if adapted to the ordinary person are hampering to the unusual mind. Is not this because we fix our attention too exclusively on the process, instead of on the result produced?"

It is to be hoped that the physicians of Massachusetts will post themselves thoroughly as to the present tendencies in the registration of nurses, that they will consider the needs of all of their patients rather than the needs of the well-to-do simply, and will join hands in an effort to provide reasonably safe nursing for the sick and suffering of all classes. Meanwhile, let us wait.

Very truly,

CHAS. H. COOK, M.D.

THE HARVARD MEDICAL SCHOOL OF CHINA.

PHILLIPS BROOKS HOUSE,

CAMBRIDGE, MASS., March 11, 1914.

Mr. Editor: This letter is intended to put the graduates of the Harvard Medical School in touch with the medical work recently inaugurated in Shanghai, China, by a group of graduates of the School.

The "Harvard Medical School of China" was established in Shanghai China, in 1913; and now has twenty-three students, a faculty of ten instructors, and occupies an excellent group of buildings, supplied free of rent for a period of years by the Chinese Red Cross Society. It is already a "going concern," and the opportunities before it for "service," which is its underlying motive, are great.

The purposes of the school are: (1) To teach modern medicine and surgery to Chinese students, and to assist in training leaders in the progress of modern medicine throughout China; (2) To coöperate with the Chinese government in inaugurating a greatly needed hygienic reform, in order to prevent epidemics spreading from there to other parts of the world; and (3) To study the diseases found in the Orient that threaten periodically the health of Occidental peoples, such as Bubonic Plague, Cholera, Leprosy, Filariasis, etc.

The work has advanced to its present stage on an annual budget of $25,000. We now face the necessity of the erection of our new hospital, and the establishment of an out-patient department. The money is already promised for the hospital building, but we need $30,000 for the purchase of the land. For the establishment of the out-patient department we are needing $5,000. An increase of $20,000 annually to our budget is also imperative.

We are now seeking for single subscribers to the above needs, and for others who will agree to become annual supporters for a period of five years. Checks for any sum will be gratefully acknowledged. It should be stated that it is expected that the work of the Institution will ultimately be taken over entirely by the Chinese. We are pioneering, and helping to set standards that will govern in the great medical advance, of world-wide importance, to take place throughout the Orient.

It is believed that, as a work of Relief, of Education, of Research, and of Prevention, it calls for the deep interest and support of Harvard men. We will with pleasure forward reports of the work to those who, at this time, are unable to take an active part, as well as to any other persons whose names you may suggest.

Very truly yours,

MARTIN R. EDWARDS, M.D.

A CORRECTION—TONSILLITIS NOT AN AIR-BORNE DISEASE.

State Board of Health, Boston, March 21, 1914.

Mr. Editor: In the issue of your JOURNAL for March 12, page 399, it is stated, concerning the recent tonsillitis epidemic in Wakefield, that "the milk and water supply have both been decided not to be the source of infection, which in this case, as is probably usually the fact, is considered to be air-borne."

This statement is erroneous, inasmuch as investigation by Dr. Frank L. Morse, State Inspector of Health, has shown that this epidemic was, with practical certainty, due to an infected milk supply, pasteurization of which was followed almost immediately by a cessation of the epidemic. Furthermore, I should question seriously any statement that the disease is probably "air-borne." In fact, all the evidence goes to show that the original infection in these epidemics arises either in some abnormal condition in the cows, or, what is more probable, in a severe tonsillitis affecting some person engaged in handling the milk.

Yours very truly,

MARK W. RICHARDSON, M.D.

CHANGES IN THE MEDICAL CORPS, U. S. NAVY, FOR THE WEEK ENDING MARCH 14, 1914.

March 4, P. A. Surgeon D. G. Allen, from Newport Hospital to Training Station, Newport, R. I.

March 5, P. A. Surgeon F. M. Munson, to Mare Island Hospital.

March 9, P. A. Surgeon R. W. McDowell, detached Naval Academy, Annapolis, Md., to wait orders at Annapolis, Md.

March 10, Surgeon A. W. Dunbar, from Washington Hospital to Fleet Surgeon, Atlantic Fleet.

P. A. Surgeon E. L. Woods, Naval Hospital, Washington, D. C.

Assist. Surgeon A. R. Barrow, to Training Station, Newport, R. I.

Surgeon Edgar Thompson, from Guantanamo Station, to Washington Hospital.

Assist. Surgeon N. McClelland, from Charleston Yard to *Hartford*.

March 12, Surgeon E. M. Shipp, from Yokohama Hospital to Puget Sound Hospital.

P. A. Surgeon F. E. Porters, from *Rainbow* to Yokohama Hospital.

Assist. Surgeon J. G. Omelvena, from Cavite Station, to home, wait orders.

Assist. Surgeon J. V. Howard, from Canacao Hospital, P. I., to home and wait orders.

Assist. Surgeon L. L. Pratt, from Olongapo Hospital, P. I., to home and wait orders.

NOTICES.

UNITED STATES CIVIL-SERVICE EXAMINATION. MEDICAL INTERNE. GOVERNMENT HOSPITAL FOR THE INSANE.

The United States Civil Service Commission announces an open competitive examination for medical interne, for both men and women, on April 8, 1914. From the register of eligibles resulting from this examination certification will be made to fill vacancies in this position in the Government Hospital for the Insane, Washington, D. C., at $900 per annum, with maintenance, and vacancies as they may occur in positions requiring similar qualifications, unless it is

found to be in the interest of the service to fill any vacancy by reinstatement, transfer, or promotion.

Graduation from a reputable medical college is a prerequisite for consideration for this position.

Both men and women will be admitted to this examination. Applicants must be unmarried.

Age, 20 years or over on the date of the examination.

Persons who meet the requirements and desire this examination should at once apply to the United States Civil Service Commission, Washington, D. C.

NEW YORK SKIN AND CANCER HOSPITAL

The governors of the hospital announce a course of Clinical Lectures and Demonstrations in the Out-Patient hall of the hospital on the following afternoons, at 4.15 o'clock.

"Syphilis," by Dr. Bulkley.

April 1. Primary lesions, genital and extra-genital—Innocent syphilis.
April 8. Early manifestations of syphilis.
April 15. Late manifestations of syphilis.
April 22. Marital and hereditary syphilis.
April 29. Treatment of syphilis.

"Cancer," by Dr. William Seaman Bainbridge.

April 30. Some practical phases of the cancer problem.

The lectures will be illustrated by cases, models colored plates, photographs, etc The course will be free to the Medical Profession, on the presentation of their professional cards.

F. HAAS, *Chairman of Executive Committee.*

SOCIETY NOTICES.

THE NORFOLK DISTRICT MEDICAL SOCIETY.—A regular meeting of the Society will be held at the Psychopathic Hospital, 74 Fenwood Road, Tuesday, March 31, at 8 p.m., sharp. Telephone, Brookline 4900.

Business.

Program:—

1. Presentation of Patients.
2. Demonstration of Charts.
3. "Remarks on Mania," Dr. E. E. Southard.
4. "Analysis of the Second Hundred Recoveries at the Psychopathic Hospital," Dr. T. H. Haines.
5. "The Incidence and Type of Hallucinations in Five Hundred Cases of Mental Disease, with Remarks on Their Differential Diagnostic Value in Dementia Precox and Manic-Depressive Insanity," Dr. A. W. Stearns.
6. "On the Influencility of the Will in Voluntary Admission," Dr. G. E. Eversole.
7. "Blood and Cerebrospinal Fluid Examinations at the Psychopathic Hospital," Dr. H. M. Adler.

BRADFORD KENT, M.D., *Secretary,*
798 Blue Hill Avenue, Dorchester.

BOSTON MEDICAL LIBRARY in conjunction with the SUFFOLK DISTRICT MEDICAL SOCIETY.—Medical section, meeting, April 1, 1913, at 8.15, at the Boston Medical Library.

PSYCHOTHERAPY.

Dr. J. J. Putnam, "The Present Status of Psychoanalysis."

Dr. L. Pierce Clark, New York, "Personal Experience in Psychotherapy."

Discussion opened by L. E. Emerson, Ph.D.; Richard C. Cabot, M.D.

E. W. Taylor, Chairman.

LESLEY H. SPOONER, *Secretary,*
260 Clarendon Street, Boston.

APPOINTMENT.

MR. ROBERT N. HOYT, '09, has just been appointed by the Corporation of the Massachusetts Institute of Technology to the position of special lecturer on Public Health Administration.

RECENT DEATHS.

DR. CHARLES BULLOCK, who died on March 16, at Arlington, Mass., was born in Providence, R. I., on March 16, 1836. He studied dentistry at Hartford, Conn., and began the practice of his profession in that city. In 1859 he removed to Cambridge, Mass., where he practised until his retirement in 1896. He is survived by his widow.

DR. JAMES N. BUTLER, who died recently in New York City, was born in 1861. After graduating from St. Francis Xavier College, he obtained the degree of M.D. from the Bellevue Medical School. Later he became a founder of the medical school of Fordham University, and its first dean. He was attending physician at St. Francis' Hospital and the Mission of the Immaculate Conception.

DR. MARCUS M. JOHNSON, who died on March 15 at Hartford, Conn., was born in 1843. He received the degree of M.D. in 1877 from New York University. He is survived by his widow and by one daughter.

DR. THEODORE R. WAUGH, who died on March 17 at Burlington, Vt., was born in 1847. He is survived by his widow and by one son.

DR. GEORGE MCNAUGHTON of Brooklyn, N. Y., died from cardiac disease on March 17, at the age of 57. He was born at Mumford, N. Y., and was graduated from Bellevue Hospital Medical College in 1878. He had practised in Brooklyn since 1881, and for five terms served as president of the Kings County Medical Society. Dr. McNaughton was a prominent specialist in diseases of women, and at the time of his death was visiting gynecologist to the Long Island College and Kings County Hospitals and consulting gynecologist to the Brooklyn, Jewish and Long Island State Hospitals.

DR. THOMAS W. MCMANUS of New York died from pneumonia on March 12, at the age of 48. He was a native of Brooklyn and was graduated from the College of Physicians and Surgeons, New York, in 1895.

DR. GEORGE O. WELSHMAN of Newark, N. J., a graduate of the College of Physicians and Surgeons, New York, in 1895, was instantly killed at East Orange on March 17 by a railroad train striking his automobile.

DR. TIMOTHEUS TAMINOSIAN, who died of pneumonia on March 13 in Boston, was born at Antioch, Turkey, in 1861. After graduating from the Central Turkey in 1884, and in 1895 received the degree of M.D. from the Jefferson Medical College. Since that time he had practised his profession in Boston.

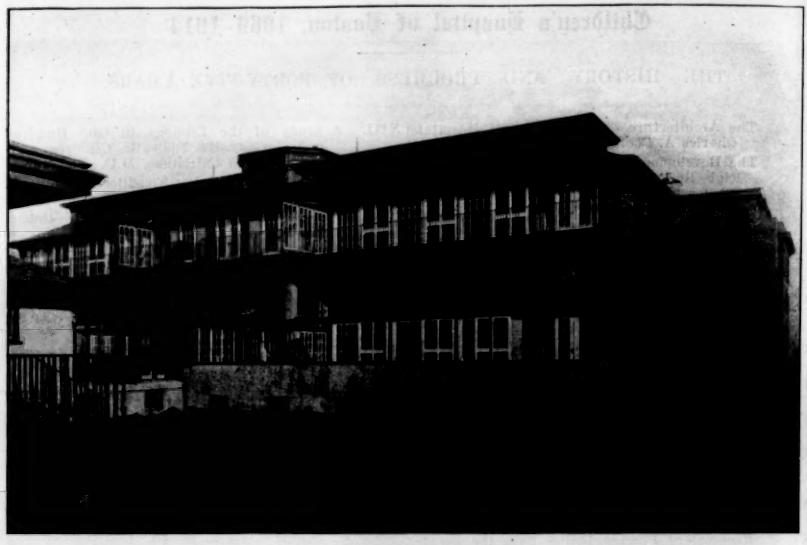
I.

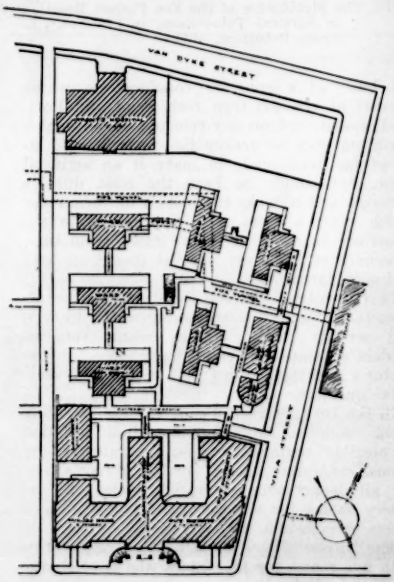
The Architecture of the Children's Hospital.

By Charles A. Coolidge, A. M.



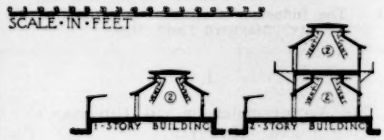
The Children's Hospital as an architectural problem was quite an unusual one. There were three separate gifts which required to be individualized and yet it was evident for the sake of convenience of administration and economy that three separate buildings should not be built. After several studies it was finally decided to build the present arrangement, which consists of an Administration Building which occupies the centre of the Main Building, from the money left in memory of Mrs. Robert Hooper, the Dispensary Building which is the portion of the Main Building to the west of the Administration Building, from the gift of Mr. F. W. Hunnewell, and the Nurses' Home, the portion of the Main Building to the east of the Administration Building, from the money left by Anne White Vose for a Nurses' Home. These different portions are separated by fire walls and are practically separate in their uses as well as in construction. These main buildings are fireproof throughout and the exteriors are built of a concrete conglomerate which consists of crushed trap rock, sand and Portland cement, without any coloring matter, which has a tendency to weaken the concrete. No attempt has been made to make it an artificial stone, but simply to have the most durable material, and to make the mass a uniform color which gives a more solid appearance to the structure than brick with stone trimmings, especially as there are a great many windows and quite large ones.

In the Administration Building are the offices, reception rooms, examining rooms, kitchen and serving rooms, storage rooms superintendent's suite, X-ray department, house doctor's quarters, ladies' aid rooms and servants' quarters.

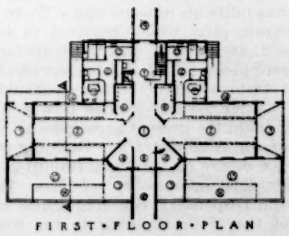


In the Dispensary Building are the receiving room, isolation suite for immediate isolation of possibly contagious cases, separate waiting rooms, examining rooms, treatment rooms, etc. for all departments, operating rooms and recovery rooms for minor surgical cases, plaster rooms, gymnasium, etc.

The Nurses' Home is built for seventy nurses with five rooms for the sisters who have charge of the hospital.



At the request of the medical staff the top floor of the Dispensary has a ward and arrange-



WARD BUILDING.

12. Corridor.
13. Laboratory.
14. Piazza.
15. Piazza.
16. Shelter.

ments for dispensary cases so that when necessary a dispensary patient can be kept there, and not taken into the regular hospital. This ward and rooms are isolated. On the top floor are also a limited number of rooms for private patients. Except the above, all the patients are in ward buildings on the pavilion plan, entirely outside the Main Building on Longwood Avenue, and connected with it by a circulating corridor which has three levels, the lower one for pipes and heat, the second which is enclosed and half above grade, for food, etc., and the upper one which is on the level of the main floor, for general circulation. The latter is screened with glass sash where necessary, and has a flat roof which can be used as an emergency fire escape.

These wards are not of fireproof construction as the lower floors are practically on the ground level and the upper floors have large balconies on three sides connected with the roofs of the corridors. It was the intention to keep the shells of these ward buildings as inexpensive as possible, so that in the future as the treatment of hospital wards changes, the trustees would not be hampered with too expensive permanent wards. This does not mean that the arrangements for the comfort of the patients, or the plumbing or sanitary arrangements are not the best, but that the wards are of rough cast instead of stone or brick. A plan and section of the double wards is shown so that it is not necessary to go into the details, but merely to call attention to certain particulars.

There are at present two two-story double wards and two one-story double wards, and locations left for two additional double wards in the future. By double wards is meant a ward on each side of the corridor on the same level. These single wards contain ten beds each with an observation room separated, making twenty-two beds in a single story building and forty-four in a two-story building.

In planning for the future increase in the number of the beds, it is the intention to place another story on the one-story wards, making them two-story wards as shown in the accompanying section.

The wards have been carefully placed so that this can be done without cutting out the sunlight from the other wards. The wings of the Main Building on Longwood Avenue have also not been carried out to their full capacity to the south, so that when the number of beds in the wards is increased, which they can be to double the present number, the corresponding departments such as the Nurses' Home, etc., can be increased in the proper proportion in the Main Building.

The method of ventilation in the wards is by a monitor top in the ceiling as well as the windows on the sides. Those toward the south are large sliding doors with metal plates attached to the doors fitting tight into a deep slot in the bottom and sides. These doors make practically an open ward in summer, and allow the beds to be easily pushed out on to the piazza to the south, which is fifteen feet wide. This piazza treatment with a narrow roof on the outside away from the building is new, and has the advantage of allowing the sunlight to enter the ward and yet protecting the patient from the direct rays of the sun and the rain. In placing the second story ward above the first story ward, the monitor form is retained in both upper and lower wards, there is no damage done to the lower ward as far as ventilation or light is concerned, as the outer wall in front of the first-story monitor is merely open lattice, so that the air has perfectly free access to the windows in the monitor top; also the balconies on the second story, which are wide, are so far above the windows in the lower ward as not to interfere with the sunlight. Each separate ward can be entered from out of doors and access cut off entirely from the main corridor, and as each ward is complete in itself, if desired there can be perfect isolation.

The main operating rooms are in a building by themselves. There is an amphitheatre seating 83, with a separate entrance for the students from the outside. This amphitheatre will probably be used for lectures rather than for ordinary surgical demonstration, which will be given in the regular operating rooms of which there are three. In the usual large amphitheatre it is very difficult for the students to see much of an operation and an endeavor has been made in the smaller rooms to place twenty-four students within five or six feet of the patient while being operated upon. This has been done by placing low galleries at six feet four inches from the floor and as nearly over the operating table as good light will permit. There is a gallery on each side of the table, on which six students sit and six stand up, with a rest, and look over the shoulders of those sitting. Thus the operating table being three feet from the floor, they are as near as possible without interfering with the surgeon and his assistants. There is a large plate glass screen between the students and the operating room proper, and a heavy iron rail prevents them from leaning on the glass

---

II.

The Development of the Hospital, with Especial Reference to the Medical Service.

By Thomas Morgan Rotch, M. D.

Report of the Board of Managers written by the Rev. Chandler Robbins, D. D. and presented to the Corporation in December, 1869, states that the original plans together with the by-laws for the Children's Hospital were laid before a few gentlemen on the 9th day of Decem-

ber 1868. An association for the establishment of a Children's Hospital in Boston was formed on the 23rd day of January, 1869, and the act of incorporation granted by the legislature in February of the same year was accepted, and the corporation duly organized on the 22nd day of March, 1869.

With the limited means at the disposal of the managers the hospital was begun in a small way. A house at No. 9 Rutland Street was bought and the Hospital was opened on the 19th day of July, 1869, and was dedicated with appropriate services on the 3rd day of August in the same year. Its capacity was 20 beds. The first patient was received on July 20th. In this house the hospital continued for one year.

In July, 1870, the managers secured by lease the estate at No. 1583 Washington Street with a capacity of 27 beds and this was occupied until 1882. In 1880 a lot of land, measuring about 31,000 square feet, was purchased on Huntington Avenue and the present building erected. It was dedicated on December 20, 1882. The medical staff was composed of a consulting board—Drs. F. H. Brown, John Homans, and William Ingalls; of physicians—Drs. A. M. Sumner, F. Gordon Morrill and J. P. Oliver; and of surgeons—Drs. S. W. Langmaid, E. H. Bradford and A. T. Cabot. Dr. H. C. Haven was Assistant Physician and Dr. Abner Post, Assistant Surgeon. Dr. W. H. Whitney was pathologist and Dr. N. O. B. Wingate was physician to the Convalescent Home. During the year the medical staff was increased by the addition of Dr. Thomas Morgan Rotch as assistant physician, and the managers, at the suggestion of the staff, appointed as resident house officers H. S. Otis and G. Haven with N. J. Knowles, Jr. as externe.

In the report presented by the managers to the corporation in 1885 and again in the reports of 1886-87 attention was called to the importance of the Out-Patient Department, a branch of the Hospital which, for some years had been doing a large amount of work in an admirable manner but in restricted quarters. In the latter part of 1886 the managers purchased a lot adjoining the former site, containing about 5000 square feet, and a thoroughly arranged and commodious building for out-patients was opened in September, 1888. The foundation of the east wing was also laid at this time.

One distinctive feature of the plan of the Children's Hospital was that it should be under the voluntary charge of the Evangelical Sisterhoods. Early in 1869 the Ladies' Aid Association was formed by the late Mrs. Chandler Robbins who gathered about her a band of devoted women and they and their successors have since constantly labored for the welfare of the institution. To them also is due the organization and support of the Convalescent Home at Wellesley.

At a meeting of the managers in 1881 it was voted to permit the establishment of memorial beds by those who desired to connect with the hospital the names of deceased children or friends.

On the 22nd of October, 1889, the east wing was opened for inspection and the capacity of the institution was increased to 96 beds. The new wing was intended mostly for medical cases, the two wards of the west wing being given up to surgical cases.

At the suggestion of the medical staff, Dr. Oliver F. Wadsworth was appointed Ophthalmic Surgeon; Dr. C. J. Blake, Aural Surgeon; Dr. H. L. Morse, Assistant Aural Surgeon; and Dr. Algernon Coolidge, Jr., Assistant in Diseases of the Throat.

Another object which the founders of the Hospital had in view was the establishment of a training school for nurses. During the year 1891 the managers carried out this plan and young women were received as pupils, the course of instruction lasting two years.

In accordance with the request made by the authorities of the World's Fair held in Chicago in 1893, it was deemed advisable to prepare an exhibit consisting of plans and views of the Hospital and Convalescent Home, reports, schedules of work performed, illustrations of treatment of patients and appliances, all of which might be of service to those interested in similar work. The plan was carried out and the exhibit shown in the anthropological department of the Fair.

It is well at this point to call attention to the reputation for excellent work which the institution has deservedly earned throughout the country among the laity as well as the medical profession. That this reputation is recognized is evidenced by the fact that during the year 1890 patients came for treatment from all parts of the United States as well as from New Brunswick, Nova Scotia, and Aberdeen, Scotland. Another evidence of the superior advantages offered by the institution is the number of physicians who come from afar to avail themselves of the clinical teaching and abundant material to be found in the wards. Interested students esteem it a high favor to be able to work under the physicians and surgeons in charge.

While it is well known that the hospital at no time had received contagious diseases, it has always been willing to bear its burden of responsibility and care for the cases which have arisen within its walls. Great precautions have always been employed to avoid such conditions. Diphtheria has always been one of the diseases to which children are more particularly liable and in 1895 much attention was given to the improving of the hygienic condition of the hospital building to guard not only against diphtheria but other contagious diseases. These investigations have been carefully followed up and in 1896 we find the bacteriology, etiology,

and the diagnosis and treatment of infectious diseases being scientifically pursued. The work on diphtheria is especially commendable and an article on the subject by Dr. F. Gordon Morrill in the Boston Medical and Surgical Journal drew wide and favorable comment. It is interesting to note that at this time every patient that entered the hospital was given an immunizing dose of diphtheria antitoxin, this being the first instance on record where such a procedure had been rigidly carried out in any institution. Since this measure has been adopted diphtheria has been practically eliminated from the hospital.

An incident of importance in the history of the hospital was the publication in 1895 of a volume called "The Medical and Surgical Report." This volume was highly commended by competent critics both here and in Europe.

In 1883, when one wing of the present building was occupied, we note that there was a daily average of 37 patients. In 1892, the year after the whole of the building was occupied the daily average of patients in the wards was 64. In 1890 the number of patients treated in the wards was 442, and in 1900 it was 1394.

In 1890 new cases in the out-patient department numbered 1,712 while in 1900 there were 2,586. In 1890 the visits to the Out-Patient department were 7,291, in 1900, 21,436, Up to 1900 there were no visits made for outdoor relief but in that year the value of this department of the hospital was fully proven and there were 1,828 house visits made by members of the hospital staff and nurses. In 1890 the number of nurses in the hospital was only 10 while in 1900 the average number was 35.

In 1902 the Board of Managers purchased three acres of land, adjoining the Medical School, from Harvard University, and it is here that the new building has been erected.

In 1904 the managers adopted the plan of including in their annual reports brief statements from the members of the Staff, giving information as to work done by the Hospital, the idea being to give a more accurate as well as a more adequate record. These records, as planned, were not to be scientific contributions of interest only to the profession, but practical statements for the information of laymen as well. This plan has been carried out and exhaustive reports in reference to work done, medical contributions, changes from time to time in the medical staff, additional departments, and various other measures by which the efficiency of the institution would be increased have been recorded.

The Hospital was the first in the country to establish at its Wellesley Convalescent Home a country branch giving to sick children the therapeutic benefits to be derived from fresh air. The Hospital has educated and trained a large group of skilled practitioners who have formed an alumni association.

In addition to its remarkable pioneer work on the immunization of diphtheria the medical staff has done much original work. To be mentioned are the modern methods of feeding, extensive Roentgen work on development and on studies connected with the time of emptying the stomach. The work in connection with the treatment of cerebrospinal meningitis is especially to be noted. Long periods of treatment of this disease by the administration of diphtheria antitoxin in one series of cases and lumbar puncture in another prepared the way for the serum treatment which has been and is so thoroughly and intelligently carried out in its wards. Lumbar puncture was first done on a series of patients in 1897 but the Flexner serum was first used in 1907.

In connection with the remarkably efficient corps of pediatricians forming the Pediatric Department of Harvard University the Hospital has rendered great aid to the complete and noted organization of this department and has opened its wards for a free study of Pediatrics to both students and practitioners. More continuous teaching is probably done in its wards than in any other hospital in the country.

The successful work of the Hospital has justified the efforts of the founders and those who have so willingly contributed to its maintenance and warrants an appeal for generous support in the future.

The writer wishes to state that he has been greatly assisted in writing this report by Dr. A. G. Helmick of Columbus, Ohio, senior house officer during his service. He is much indebted to Dr. Helmick for the large amount of work which was necessary to bring these facts, connected with the hospital, together.

III.

The History of the Children's Hospital with Especial Reference to the Orthopedic Department.

By R. W. Lovett, M. D.

The Children's Hospital was founded in July, 1869, and began in a very small way, treating only 12 medical and 18 orthopedic and surgical patients in the five months of the first year's activity. The staff consisted of three physicians and three surgeons, the latter being Drs. Francis H. Brown, S. W. Langmaid and John Homans. In the year 1870, however, it may be seen that the work was still very light, for only 30 medical and 39 orthopedic and surgical patients were treated in that year. In 1874 an out-patient department was opened.

In 1877 Dr. Francis H. Brown retired as surgeon, and was replaced by Dr. William Ingalls, who had been up to this time one of the

physicians. In 1876 Dr. Homans retired from the staff, and his place was taken by Dr. E. H. Bradford, who began then a service as surgeon which terminated only with his retirement in June, 1912. In this service of nearly thirty-five years he saw the hospital rise from its very small beginnings to an institution of national reputation, and in this progress he was one of the important factors. No one else has had so long a connection with the staff.

In 1879 Dr. Arthur T. Cabot was appointed assistant surgeon, and he became surgeon in 1882, a position which he held until his resignation in 1889. Dr. Brown and Dr. John Homans were made consulting surgeons in 1879, and Dr. Ingalls in 1880. Dr. Abner Post was appointed assistant surgeon in the same year.

In 1883 the hospital moved to the building on Huntington Avenue, at that time a modern, capacious and up-to-date hospital, which has now become so wholly inadequate to the present demands on it. In the first year in the new building, however, only 178 orthopedic and surgical cases were treated. In this year Drs. F. S. Watson and H. L. Burrell were appointed assistants in the surgical out-patient department.

With the move to Huntington Avenue there began what one might call the modern history of the hospital, that is, a rapid expansion in its work and usefulness. For example, in 1883 there were treated in the wards 299 patients and there were 1488 out-patients, while in 1903, twenty years later, there were treated in the wards 1505 patients and in the out-patient department there were 6341 new patients.

Dr. Langmaid resigned as surgeon in 1885, and was made surgeon to the throat department in the following year. Dr. Post became surgeon in 1886, and Dr. Watson resigned, while Dr. Burrell was made assistant surgeon. Dr. H. W. Cushing was in this year made an out-patient assistant. In the year 1887 Dr. Post resigned, Dr. Burrell took his place as surgeon, Dr. Cushing became assistant surgeon, and Dr. R. W. Lovett became out-patient assistant.

In 1889 Dr. Cabot resigned as surgeon, and his place was not filled. Dr. Burrell remained as surgeon till his death in 1910, and his place as surgeon was filled by Dr. James S. Stone in 1912. Dr. Bradford resigned in 1912, and was succeeded by Dr. R. W. Lovett. Other members of the present orthopedic or surgical staff are as follows: Associate surgeon, Dr. Augustus Thorndike, connected with the department since 1897; assistant surgeon, Dr. Robert Soutter, becoming a member of the assistant staff in 1903; junior assistant surgeons, Dr. Albert Ehrenfried, appointed in 1910, Dr. Arthur T. Legg, appointed in 1908, and Dr. James Warren Sever, appointed in 1908. In the department of general surgery the junior assistant surgeons are Dr. Charles G. Mixter, connected with the hospital since 1911, and Dr. William E. Ladd, appointed in the same year.

In the intervening years the roll of other names connected at some time with the orthopedic or surgical work of the hospital as members of the assistant staff is a brilliant one. These names are Dr. E. G. Brackett, Dr. J. E. Goldthwait, Dr. John Dane, Dr. E. H. Nichols Dr. R. B. Osgood and Dr. Z. B. Adams.

In 1903, by an arrangement made between Drs. Bradford and Burrell, the surgical service, which up to that time had been indiscriminately orthopedic, and general surgical, was divided into two divisions, one orthopedic and the other general surgical, Dr. Bradford taking the former and Dr. Burrell the latter. This division proving eminently an advance, it has been continued as a permanent division of the work.

The orthopedic service has shown the benefit of this division and the consequent better specialization in its own work by an increase in the volume of its work, and in the productiveness of the service. In the six years ending in 1912 this department contributed to literature three text-books and 91 articles in periodical literature. It gives 300 hours of clinical teaching to the students of the Harvard Medical, beside eight courses to graduates.

The orthopedic service is an active one, and in the year 1913 each orthopedic bed was occupied on the average 23 times in the year. Compared with a similar hospital in another city devoted largely to orthopedic cases, each bed in that institution was occupied five times in the year 1911. This efficiency of service is made possible only by the use of the Convalescent Home at Wellesley, opened in 1875, which has been maintained since then by the Ladies' Aid Association of the hospital, who have thus for some thirty years contributed so greatly to the advance of the hospital.

The growth of the orthopedic service may be shown by the fact that in 1913 the orthopedic operations numbered 423, an increase of 60 per cent. over the number in 1906, and in 1913 the orthopedic admission showed an increase of 41 per cent. over similar admissions in 1910, the figures of which happened to be available for comparison.

If the progress of the past offers any basis for judging, we may look forward to a great institution. In 1870, the first full year of the hospital, there were six medical men on the staff, no out-patient department, and 83 patients were treated. The running expenses were about $6,000. In the year 1912, thirty-two years later, the members of the consulting, visiting and assistant staff numbered 46, the visits to the out-patient departments numbered 26,500. 1,729 cases were admitted to the wards, and the expenses were $54,800. With the financial support of the public in maintaining the new hospital we may well see that a more rapid rate of enlargement and usefulness lies ahead of us in every department in an institution so admirably equipped as the one to which we are soon to move.

IV.

The Work of the Children's Hospital in 1913.

By John Lovett Morse, M.D.

The work of the Children's Hospital has increased steadily from year to year in spite of the fact that the accommodations for the treatment of patients have remained the same during recent years. During the year 1913, 1,750 patients were admitted to the wards. These were distributed as follows:

Medical	569
Surgical	522
Orthopedic	569

The daily average of patients in the hospital during the year was 70. The large number of patients admittted compared with the number of beds was rendered possible by discharging the patients as soon as it could be done without injury to them and by sending them to the Convalescent Home in Wellesley to regain their strength.

One thousand six hundred and forty-one operations were performed during the year. These were divided among the various operating services as follows:—

Surgical	483
Orthopedic	422
Throat Department	736

The operations, both on the surgical and orthopedic services were, of course, of the greatest variety. Those of the throat department were largely the removal of adenoids and tonsils, although many more serious and difficult operations were performed by them also.

The medical out-patient department is open daily, in the morning. The surgical and orthopedic out-patient clinics are held four times a week, in the afternoon. The clinic for nervous diseases is held twice a week, in the afternoon, and that for diseases of the throat, three times a week, in the afternoon. There is also a special clinic for the treatment of lateral curvature four times a week. A special clinic for the treatment by muscle training of neurological cases and of orthopedic cases suffering from paralysis has also recently been established conjointly by the orthopedic and neurological departments. This clinic is held four times a week, in the afternoon. The number of patients treated in the out-patient department was as follows:——

New patients in out-patient department	6059
Medical	2416
Surgical	1193
Orthopedic	957
Lateral curvature	64
Nerve	327
Throat	1102
	6059

Whole number of visits made	27,153
Medical	8006
Surgical	4319
Orthopedic	6893
Lateral curvature	2896
Nerve	3038
Throat	2001
	27,153

A very important department of the hospital, and one which is absolutely indispensable to the orthopedic and surgical services, is the surgical appliance shop. This department manufactures all the apparatus which is used in the treatment of orthopedic and surgical cases both in the wards and in the out-patient department, and also does a certain amount of work for other hospitals and outside physicians. It has eight employees and during the year did a business aggregating nearly eleven thousand dollars. The shop supplies the apparatus at very nearly cost, thus saving the patients considerable amounts of money.

The social service department has been even more active during the last year than ever before; 696 new cases were referred to the department during the year. These, added to the number carried over from 1912, make a total of 1500 families with which the hospital has been kept more or less closely in touch. The number of visits made was 3075.

The school of nursing is of very high grade. The course is for three years. The school is of the first rank, meeting the requirements of the Board of Regents of New York state. Its graduates are eligible for membership in the Massachusetts State Association and in the National Association of Trained Nurses.

The amount of instruction given by all the departments both to physicians and undergraduates in medicine has steadily increased. Physicians come to the hospital for instruction from all parts of the United States and Canada, as well as many from foreign countries. The students in the third and fourth years of the Harvard Medical School are in the wards almost daily. The value of the instruction given in this way can hardly be overestimated, since it extends the usefulness of the hospital far beyond its walls and to many children who have never seen or heard of it. A special series of lectures was given by the orthopedic department to

physicians at a minimum fee during the year, and a series of free clinical lectures by all the departments of the hospital to the Boston school nurses and the nurses of the Instructive District Nursing Association.

V.

ORTHOPEDIC SURGERY AT THE BOSTON CHILDREN'S HOSPITAL. A REVIEW OF THIRTY YEARS OF CONTINUOUS SERVICE.

BY E. H. BRADFORD, M. D.

THE progress in the development of the science and art of orthopedic surgery in the past thirty years has been reflected in the work in that department of surgery at the Boston Children's Hospital.

In addition to this, valuable experience has been collected from the work of the many trained observers at the hospital, and as a result deductions have been made and methods of treatment tried, rejected or accepted.

A complete review of the work would be unnecessarily detailed but a condensed statement of conclusions which seem justified may be of service.

TUBERCULOUS AFFECTIONS.

One of the most gratifying changes in the last 35 years in connection with the Hospital is that shown in the great improvement in the results obtained in the treatment of the tuberculous bone and joint affections.

Anyone who can recall the pitiful condition of the cases brought for hospital care in the early days, and their unsatisfactory state when discharged, will view with much satisfaction the results of treatment observed at present. It cannot be claimed that the ultimate goal has been reached, and much greater benefit will undoubtedly be recorded in the next generation, when more thorough measures of combating the invading disease, or strengthening the patient's resistance, have been discovered, but a more surprising improvement is to be recorded now than that formerly possible.

This is due to several factors, viz., greater skill in the early diagnosis of cases; more systematic and thorough treatment carried on continuously for as long a period as is necessary, and greater care in the stage of convalescence.

TUBERCULOSIS OF THE SPINE.

Dr. Sayre's boast, that there will be no more hump-backs, appears to have been justified by the results obtained when careful treatment is feasible. Certainly the cases brought to the in-service at the Hospital do not now show the distressing deformities which were the rule 30 years ago. There appear also to be fewer resulting abscesses than was the case formerly.

Improved methods of fixation on recumbency frames permitting rest without imprisonment, and locomotion with protection from jar, including head and trunk fixation by plaster and leather jackets, efficient appliances which increase the cures within the control of the surgeon. It may be said now to be a demonstrated fact that no case of caries of the spine where an early diagnosis is made and proper treatment furnished for a sufficient length of time need develop a noticeable deformity; but for such a thorough treatment and such satisfactory results not only a mastery of details is needed, but also a control over the care of patients for a relatively long period. Such a course of treatment does not necessitate hospital detention or even special skill in nursing but the care of a mother or nurse capable of carrying out the required directions. In fact, the care by an intelligent mother may be superior for these cases to that of an overworked nurse whose ward duties may interfere with detailed oversight and attention to important details.

For a choice between ambulatory treatment and recumbency, or locomotion with protection by plaster of Paris jacket fixation, braces with or without head supports, as well as for a selection of the form of brace or the method of application of plaster jackets, the surgeon is guided by the means at his command and the circumstances of the case, as well as by nursing and environment at command. The employment of brace without adequate skill in their design or application does not lead to the best results. Recumbent treatment without fresh air is objectionable. Plaster jackets improperly applied or used without judgment are both untidy and inadequate.

The following suggestions are to be kept in mind. The purpose of all treatment being to keep the diseased bodies from being bruised together by the superimposed weight, recumbent treatment is the best method, unless the disease is situated in such a part of the spine that it is possible to throw the superimposed weight more upon the firm and undiseased portion of the spine, *i.e.* the articular processes, and to prevent all motion forward at the diseased portion of the spine, or at least to limit it to such a degree that no injurious bruising occurs.

Manifestly, rigid recumbent treatment is more needed in a case when a large region, including many bodies is attacked than where only a small focus or an area surrounded by firm bone is diseased. In recumbency it is necessary to arch the spinal column forward and for this a firm pad (sawdust bags are the most serviceable) on a firm but not too hard surface is needed. This is adjusted to the back at the level of the disease and can be made to serve well if the recumbent

frame holds the patient in place. A plaster of Paris posterior shell, applied when the patient's spine is pressed forward at the diseased point, gives a back support to which the patient can be well secured. In children it is well to place them upon the usual bed frame in addition, to prevent the twisting of the spine by leg kicking.

In cervical caries, head traction, and in psoas contraction, leg traction, is needed, but the amount of pull should not be great when an increasing abscess is to be feared.

Details as to the various methods of applying jackets, or of the braces used must be left to the judgment of the surgeon. Certain common errors are to be avoided, viz., in plaster jackets, the omission of a head or neck support; neglect to carry the jacket down far enough in front; the application of a jacket which holds the patient forward rather than throws him back; or which does not throw the spine back at the point of disease; the application of braces, which do not exert adequate forward pressure at the point of disease, or do not hold the spine firmly enough either because of too light material, or from improperly applied straps.

In the question as to the length of time when recumbency or protective treatment is needed the surgeon has no guide but his own judgment. The presence of muscular spasm, the guarded movements of the patients when free from support are indicative of the instinctive need of support or protection. This differs from the feeble movements of a child just released from recumbency, or from a jacket or brace.

The X-Ray shadow is not an absolutely reliable guide in directing the treatment of spinal caries and the possible release from protection, even where satisfactory pictures can be taken.

New, firm bone may be present although penetrable by the rays, as in the case of the patella, which is often not shown in a front view of the normal knee joint.

That excellent results can be obtained with permanent cures without deformity, with recession of deformity, has been abundantly proved by the Hospital records. The subsequent history of cases severely attacked in childhood have in some instances been known in adult and married life, with the birth and growth of healthy children.

The operative treatment in Pott's Disease consists in opening the abscess and, recently, in the attempt at spinal fixation by bone graft and periosteal flaps.

In regard to the treatment of abscess, it can be said that sound practice seems to consist in abstention from incision as long as the abscess does not increase, or occasions no harm. Complete absorption of some large abscesses has been observed in many instances. But this conservatism is to be supplemented by radical treatment where incision is necessary. This should not only be free, but carried out so as to allow free discharge as near the original source as possible. To aid in this the surgeon will find a large steel uretheral sound of use in finding, and as a guide to the proper points of incision. Multiple incisions in the back, side, and front are often needed to drain a psoas and lumbar region properly. In some instances, costo-transversectomy is needed to drain an abscess in the post mediastinal region, which caused distressing and alarming attacks of dyspnoea. The operation is not difficult, though it is sometimes not easy to palpate and tap the abscess after the opening through the thoracic wall has been made, if the abscess is well forward on the front of the vertebrae.

The injection of germicides into abscesses in Pott's Disease without provision for drainage has not found favor in the Children's Hospital wards. A few unfavorable cases may have prejudiced the observers.

The attempt to ankylose the back of the spinal column by bone transplantation, or by causing ankylosis of the spine, is so recent a procedure that sufficient clinical evidence has not yet been secured to justify a critical estimate of the permanent value of a method. It certainly seems to promise much in shortening the period of treatment.

TUBERCULOUS DISEASE OF THE HIP.

What has been said as to the results now obtained in tuberculosis of the spine can be repeated with equal truth in regard to tuberculosis of the hip.

There is less deformity, fewer abscesses, and less bone destruction in the cases sent into the in-service of the Hospital for treatment, than was formerly the case. Much better results are obtained now than formerly.

This has been shown in the statistics of the results in cases treated in the Children's Hospital, five or ten years after the end of treatment as compared with the former results, and there is reason to believe that at present even better results can be expected.

The problem, however, of the treatment of hip disease is not a simple one, but requires more thought than the treatment of caries of the spine with modifications to fit the varying conditions. Operative interference, attacking the bone in caries of the spine is admittedly impracticable, but in the hip, the natural inclination of the surgeon is to shorten the difficulty by radically eliminating the disease by excision, erosion, removing tubercular foci. The experience of the Children's Hospital in the past 30 years, after a careful trial of both operative and conservative methods, coincides with the experience in many other clinics, in the opinion that where conservative methods can be systematically carried out, which, with proper organization of Hospital, out-patient department, out-door relief, convalescent country homes, are entirely possible —much better results follow than if the eradica-

tion of diseased foci is attempted by operative measures. Surgical Tuberculosis of bone is a constitutional disease with local manifestation. Surgical intervention should be directed to meet the local indications, preventing bone bruising, pain, deformity,—promoting drainage of detritus, and the reparative bony healing, almost sure to occur if fresh air and as much activity as the lesions permit. To cage children in beds, in hospital wards, in heavy plaster bandages preventing locomotion, are measures which may be necessary for a time, but the time should be as brief as possible and, fortunately, in a large majority of cases in children, unless the disease has reached an advanced stage, the time of imprisonment need be short. The surgical indications for prevention of deformity, bone trauma can be met while the patient enjoys comparative freedom in locomotion.

The tuberculous bone process as has been abundantly shown in pathological specimens, not being rapid in its progress, permits and stimulates a conservative bone reaction in the adjacent tissue which if conditions are given, eventually heals. This healing is delayed by injury to bone tissue, as is inevitable in operative surgical interference involving bone destruction. Such interference may be at times necessary when the carious detritus can not escape and acting as an irritant, promotes progress of the disease, where the amount of detritus is too great for absorption, and where no escape is possible. The true *vis medicatrix* in hip disease, as in tuberculosis elsewhere, is the antidote which Nature furnishes in an improved environment. Naturally more can be expected in the way of recovery in children than in adults, both because the reparative power is greater in the former, and a longer period is needed for repairs, and because it is more easy to control favorable conditions of environment for children than for adults.

Early excision; excision of the acetabulum; partial excisions; channeling for foci; are not procedures which are to be recommended for tubercular disease of the hip in children, according to the experience of the Children's Hospital.

As a life saving measure in neglected cases amputation at the hip, in extensive pelvic disease, has been done 4 times in the early period of the Hospital, when more neglected cases were brought for treatment. In one, the patient was known to live to manhood, enjoying excellent health. In two others, death from amyloid disease followed several months after recovery from the operation. In a fourth, the ultimate result was not known.

Operative dislocation of the hip, to relieve interarticular pressure in advanced acetabular disease, was performed three times with benefit and in one instance, the case was followed to adult life, a complete cure resulting with deformity not yet corrected, but perfectly correctable by osteotomy.

The present routine treatment at the Children's Hospital consists of a bed frame, and traction during the acutest stage, the early application of the abduction traction splint which furnishes better fixation, allows more locomotion, and less bone atrophy than a plaster spica bandage; the use of this with crutches during the florid stage of hip disease followed by a perineal crutch, and weight bearing gradually permitted, according to the progress of the disease toward recovery.

Increasing abscesses are incised, existing deformity corrected either under an anaesthetic or by pull; osteotomy being reserved for healed cases with deformity.

Under such treatment subluxation should be prevented, abduction and flexion also, though in rapidly growing children the prevention of these, especially a flexion deformity, demands protection and limitation of weight bearing for a long period until the epiphyseal bone has regained the required firmness.

TUBERCULOSIS OF KNEE, ANKLE, SHOULDER AND ELBOW.

The conservative treatment of these cases in children seems justified in preference to the operative removal of bone, other than sequestra or detritus. Plaster and leather fixation, with a Thomas knee splint for the knee and ankle, with fixation for the elbow, eventually give as satisfactory results as can be obtained. The course of treatment is, however, regrettably slow, and the use of some methods of early constitutional cure, besides that which comes from protection from trauma and the natural power of repair of the individual, is much to be desired.

These affections are treated successfully on the same principles mentioned in regard to treatment of caries of the spine and hip disease, but the treatment is modified by the varying anatomical and physiological conditions. In the upper extremity the problem of weight bearing being removed, the treatment is simplified, in the shoulder, the drag of the weight of the arm prevents bone crowding, but the spasm of the strong pectoral muscles draws the arm to the side, and furnishes the indication in fixation for an angular axilla pad.

KNEE—ANKLE.

In the lower extremity Thomas' well-known splint, with its modifications is of recognized service, but it should, in the acuter stage, be supplemented by plaster of Paris or leather fixation.

Radical operative excision should never be resorted to in tuberculous disease of the knee in growing children.

In disease of the ankle, subperiosteal removal of an extensively diseased astragalus sometimes shortens the course of the affection but statistics have appeared to show the best results following

Fig. A.—Abduction traction splint padded. (Bradford.)

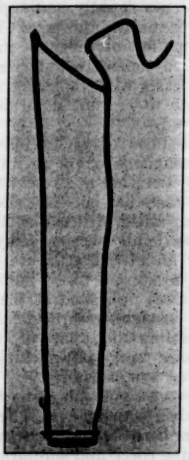

Fig. B.—Abduction traction splint without padding or straps. (Bradford.)

Fig. C.—Child wearing the abduction traction hip splint. (Bradford.)

Fig. 10.—Rear view of the abduction traction splint applied. (Bradford.)

Fig. F.—Model showing lack of fixation when traction is not applied.

Fig. G.—Model showing lack of fixation of hip-joint by plaster spica from the necessary looseness at the pelvis and trunk.

conservative protective treatment, *i. e.*, plaster bandage fixation and a Thomas splint to prevent the injury from weight bearing, in locomotion.

FRESH AIR TREATMENT.

In all tuberculous affections of the joints the chief reliance for cure must, at present, be placed on the tonic of absolutely fresh air whatever may in the future come from vaccine or serum therapy.

The statistics of the Convalescent Home of the Children's Hospital have demonstrated clearly not only that fresh air is beneficial in tuberculous bone cases as in tuberculous affections of the lungs, but that it has a tonic value. Hospital cases removed to fresh air shacks increase in weight, appetite and color; while the physiology of this is not clear, the fact can be regarded as demonstrated.

It would appear that sea air is not superior to that of the fields. It is important that the air should be fresh during the night as well as the day.

OSTEOMYELITIS FROM PUS-MAKING GERMS.

Thirty years ago the distinction between the different forms of caries of the bone were not known and as the relation between osteomyelitis and certain germs had not been studied, the fact that the pathological history of the affection caused by the invasion of the tubercle bacillus differed from that caused by the irritation of the several forms of cocci, or that the latter differed was not understood. While the matter is as yet one which demands much more investigation, enough is known as to the two groups of bone infection to base different policies in treatment.

The fact that as a rule osteomyelitis from the pus causing cocci attacks the diaphysis, and that from the tubercle bacillus involves the region of more rapidly growing bones; the epiphysis or juxta epiphysis, *i. e.*, the diaphysis at its junction with the epiphysis is sufficiently established to be accepted as a rule, with exceptions, and indicates that in the slower developing tuberculins more attention needs to be paid to the prevention of deformity than where the marrow of the shaft is attacked, with its stronger and less rapidly growing and less rapidly cicatrizing bone. In the cocci group of osteomyelitis the indication for drainage is the chief one, whereas, in the tuberculous osteomyelitis the chief purpose of the surgeon is to put the tissues into such a condition that the reparative process may obliterate the destructive otitis.

In fulminating cases of osteomyelitis the indications are clear, viz. the region of invaded bone should be found, incised, and the bone drilled. High temperature and blood count are to be observed with marked constitutional symptoms and usual local oedema, or swelling at the point attacked.

In the arthritis of infancy, so called, an acute affection, the pathology is not well understood, except that joint destruction, especially of the hip occurs rapidly and suppuration takes place and the invading germ is not the tubercle bacillus, but of the pus-causing group of cocci.

Speedy operative interference is demanded in these cases with the early use of a traction appliance to prevent deformity where the hip is involved.

The form of caries following typhoid fever or pneumonia offers an interesting field for investigation, but at present the clinical course of these cases has not been adequately studied, nor has an allied, distressing ailment where several of the joints become ankylosed and distorted after an attack of acute severity, marked by pain, prolonged fever, but without suppuration. The cases presented at the Children's Hospital have brought records of a prolonged sickness resembling in some of its clinical features typhoid fever, but lacking the distinctive intestinal symptoms.

Cases of multiple bone tuberculosis, cases of mixed infections, *i. e.*, where an original tuberculous bone lesion has been invaded by the pus-forming cocci, and suppurating osteomyelitis has resulted, with such sequelae as to make the original nature of the affection uncertain, have naturally been not infrequent, indicating the need in the future of carefully recorded details of the initial condition of the patient.

It may be said that the prognosis of these cases in children is surprisingly good, when favorable nursing conditions can be furnished.

RACHITIC DEFORMITIES.

As the Children's Hospital has been for many years the chief clinic here for the treatment of rachitic deformities it is to be expected that marked progress has been made in the different methods of treatment in this most common affection.

Formerly, operations upon bone were regarded as a dangerous undertaking, and children were subjected to a tedious treatment with heavy and cumbersome apparatus, with but little prospect of substantial improvement in resistant cases.

The introduction of aseptic measures has made osteotomy safe; osteoclasis is easily performed, and simple appliances adapted to younger and less resistant cases are of service. The X-Ray enables the surgeon to determine the character of the deformed bone, and a more careful and extended knowledge of the clinical history of cases, made possible by large and well organized hospital clinics, have taught that in a large majority of cases the tendency is to a rectification of the deformity in growing children if the conditions favoring help are given. All this com-

bined makes the treatment of these deformities a matter of no great difficulty.

Modifications of the Thomas knee splint can be made for use at night for such young children as require correcting pressure; light walking, correcting appliances can be used where necessary in deformities not suitable for operation and with threatening increase of curves, as a rule cases older than 4, with marked curves should be operated on. Osteoclasis by means of an osteoclast is more precise than manual osteoclasis, and osteoclasis is a simpler operation than osteotomy and therefore preferable in bow-legs. Osteotomy is preferable where correction near the knee or hip is required as in knock-knee and coxa vara. Subcutaneous osteotomy in skilled hands can be made as precise as through a skin incision and is preferable as being simpler. Linear osteotomy, and no further injury of the periosteum makes blood clot healing certain, and if the bone is divided three-fourths through the shaft and the rest broken, the interlacing fibres of the periosteum secure speedy bone healing and allow proper rectification of deformity. Perfect allignment is not necessary, but correction permitting weight bearing in an improved position is followed by further rectification through normal growth.

Anterior tibial curves can be treated without wedge-shaped bone exsections by linear osteotomy of half of the bone and straightening, with blood clot healing of the resulting gap, with or without tenotomy of the tendo Achillis to overcome the bow-string tension on the curve.

Experiments have shown that linear section of a part of the bone is made by osteoclasis. The bone cracks cleanly on the side opposite to the pressure with slight tearing on the proximal side; there is no danger of splintering or shearing in long bone. In osteotomy properly done the clean section is at the point of attack by the osteotome, and any irregularity in the division occurs where the section is completed by manipulative correction. Danger to the arteries and nerves is reduced to a minimum in osteotomy if the osteotome is driven directly through the nearest point to the bone cortex and by manipulating the osteotome the bone undermined from the inside until complete fracture is possible by manual force. A small osteotome will be found preferable over a large one by a surgeon used to the procedure.

In some instances manual correction of rhachitic curves will be found more easy if the limb has been bandaged by a plaster bandage, worn for a month. Bone atrophy takes place. There is, however, no advantage in this method of procedure over osteotomy.

Of the various forms of osteoclast the well known Rizzoli's appliance has been found reliable and practicable in the clinic. Simple and effective also is a modification of Little's osteoclast.

After correction, the limb, protected by cotton wadding, or a soft bandage, is held in plaster of Paris fixation for a few weeks, after which as a rule the bone is firm. It is advisable that the plaster bandag · be bivalved so that the front of the limb may be inspected at will by the surgeon without disturbing the position. If the plaster bandage is a broken one this can be done without weakening the fixation of the fragments and the surgeon may reassure himself as to the position of the fragments and the proper correction of the deformity.

PARALYTIC DEFORMITIES.

In no branch of orthopedic surgery has there been so surprising an improvement as in the treatment of the deformities of · anterior poliomyelitis.

The former treatment consisted simply in the endless and unbeneficial application of Faradic electricity and massage, and awkward and, in the main, useless appliances with the aid of tenotomy of the tendo Achillis in a few instances.

Improvements in appliances have enabled the surgeon, through purely muscular treatment, to secure improvement in the weakened but not paralyzed muscles by the exercise given in locomotion with light appliances permitting, as far as possible, motion in all directions except in the direction of deformity. The essential in paralytic affections of the lower extremity is to place the child on its feet with frame, crutches, or other appliances giving it the sense of locomotion and activity. Deformities are easily corrected by tenotomy, aided by osteotomy in extreme cases, with forcible corrections, and in some cases open incision.

POLIOMYELITIS.

It is an interesting fact in the history of medicine that an interest in the study of poliomyelitis should have been developed acutely and suddenly all over the medical world in the last five years although the ravages of the disease itself have been common always, and there is no reason to think that the affection is more prevalent now than heretofore. It is to be hoped that renewed investigations will bring forth remedial measures which will control our surgery of deformities. It is also singular that this affection was almost ignored in the medical instruction of fifty years ago, except a mention of what was classed as teething palsy, or infantile paralysis.

The treatment of the deformities of poliomyelitis if described in detail would demand a volume in itself for adequate presentation, as the manifestations vary greatly, and much persistency and some ingenuity are needed to furnish the substantial practical relief which may often be given by the surgeon in the correction, the prevention of deformities, and in the utilization of damaged limbs.

A brief statement of the principles involved in the measures to be selected may serve to illustrate the advance made in the last 30 years in combating this affection.

The disease itself displays in most instances at first a marked effort for recovery, for 6 months or a year, and later a tendency to develop deformity from the enforced misuse of the damaged limb. The position in which a dangling limb is held, from constant or gravity position, strains certain weakened muscles and permits contraction of unopposed muscular groups. The superimposed weight falls faultily upon the damaged foot and makes a distortion which becomes permanent with growth. Although at the outset only certain muscular groups are permanently paralysed, many muscles being weakened, and others impaired in their strength by a lack of use, the principles of treatment demand, when it becomes evident that no recovery is to be expected in the muscular groups inevitably damaged, giving such freedom to the limb as may approach the normal and develop strength in supplementary muscles to make up for deficient function.

In the correction of deformity the measures needed are simple: gradual or forced stretching of the contracted muscles, aided or not by tenotomy, myotomy, ar even osteotomy, as may be necessary, in order to give the most favorable, useful bearing alignment of the bony structure possible.

Apparatus of the simplest character which is effective is to be furnished to aid proper weight bearing and to check contraction of an unopposed group of muscles.

For the partial restoration of functional activity the employment of muscle transference is of great value and the use of artificial ligaments to check the flail joints has proved of great value.

In cases where no muscles are left unparalyzed and muscle transference is impossible, stiffening the joints by partial excision of the cartilaginous surface, or in paralytic calcaneus, the removal of the os calcis and slipping the foot back, thus checking heel drop are successful procedures.

The details of these measures would form a chapter in themselves. Here can be recorded the fact that few cases of infantile paralysis of a lower extremity need remain unrelieved. Complete restoration of function is not possible, but the children can be freed from imprisonment, to a wheel chair.

SPASTIC PARALYSIS.

Little's Disease was formerly treated by massage and appliances as it was regarded as a central nervous affection, cerebral paralysis with a lesion in the cortex. The neurologists considered surgical treatment irrational and absurd, but empirically orthopedic surgeons proved the contrary, Dr. Gibney of New York and the surgeons at the Boston Children's Hospital being among the first.

It is now known that tenotomy and myotomy, or muscle paralysis surgically induced, followed by muscle training, presents a feasible method of treatment followed by benefit.

The affection being one of disturbed muscular balance the temporary paralysis of the muscles with exaggerated muscular spasm and the development of the overpowered muscles, accompanied by appliances making locomotion possible and correcting a tendency to a relapse of the deformity, is always followed by improvement, in cases that are not mentally defective. Experience has shown that there is a tendency to a gain of muscular control in all these cases if a stimulus to muscular effort is furnished. The removal of deformity removes an impediment to muscular exertion.

Correcting appliances without tenotomy are of little use in these cases. A long after-treatment, muscle training, is to be expected.

Alcohol injections paralyzing the nerve, bringing an exaggerated impulse in addition to the measures correcting the deformity, has appeared to be of advantage, but the exact value of the procedure is still *sub judice*.

Cutting the posterior roots in children who can be helped by milder measures is with our present experience not justified. The mortality of the procedure in children, cannot be disregarded except in the severest cases

ANKYLOSING ARTHRITIS. ARTHRITIS NODOSA.

While degenerative arthritis, the degenerative changes of middle life or old age, the spavin of animals is not seen in children, an affection often confounded with it though pathologically different is occasionally seen in a distressing form in children. It is polyarticular and in this differs from joint tuberculosis. There is usually a painful stage, there is disability and distortion.

While a scientific method of treatment of ankylosing arthritis has not yet been developed many cases at this hospital has shown improvement and in some of the milder cases recovery after a system of treatment directed to the correction of the deformity, steadying the limbs if in the painful stage by plaster of Paris bandages, using apparatus, there is recurring deformity and apparatus, with treatment stimulating the circulation locally; greater improvement in methods of treatment may be hoped for if advances in bio-chemistry succeed in throwing more light upon the nature.

Although this affection has been much studied under different names and has been supposed to be of a tonic nature, the exact nature of the toxin has not yet been established, nor in fact that it was not due to some defect in mentabolism, *i. e.*, an anti-intoxication.

While it is more frequently seen in adults

(in the writer's experience in women) some of the most pitiable cases occur among children, even in infancy.

In other instances the affection appears in children in a much milder form and is followed by gradual recovery, apparently aided by the treatment.

After it became established that certain joint tissue change affections and disabilities result from a degenerative process in contrast to the destructive inflammatory carious processes caused by the entrance of definite germs, it appeared that the treatment needed was to stimulate the tissues rather than to promote tissue atrophy from rest and fixation.

Where active inflammation is not present, the amount of use should be all that is practicable within the limits of discomfort and violence or the trauma of strain. Gradual use under proper proportions is beneficial, aided by such measures as stimulate the circulation, *i. e.*, massage, especially vibratory massage, dry heat, electricity, static, the intermitent current, hydrotherapy, passive exercises, but especially active exercises, weight bearing, carefully directed.

An unexpected amount of improvement will often follow these methods of treatment persistently carried out, accompanied by proper attention to metabolism.

This combined with corrective or prevention of deformities and the protected use of the limbs guided from strain if necessary by crutches or light apparatus, form a practicable system of treatment which must serve until increasing knowledge may furnish a most positive method of cure.

CLUB FOOT.

The treatment of congenital talipes equino varus 40 years ago was successful in many instances, but the methods were clumsy and the need of thorough after-treatment was not recognized. Relapse and incomplete correction was too commonly the result.

The morbid anatomy was not well understood. The Scarpa shoe formerly much used may be taken as an appliance imperfect for correction and impossible as a walking shoe in after-treatment. Removal of the cuboid, astragalus, and wedge-shaped excision of the tarsus, all mutilating procedures, had been occasionally employed and even amputation performed in resistant cases.

At present all cases of club foot from infancy to adult age are to be regarded as curable without mutilation and with the restoration of normal function. It is, however, necessary to meet certain definite indications fully and thoroughly.

The affection is a congenital displacement of the bones of the foot chiefly at the mid-tarsal articulation, with adapted alteration in the soft tissues, ligaments, tendons, and in the shape of the cartilage and bone in the joint surfaces of the astragalus and os calcis. Roughly, the deformity may be regarded as a congenital inward subluxation at the mid-tarsal articulation.

Treatment in brief consists in the gradual or forcible correction of the misplaced bones with retention in an overcorrected position for a sufficient length of time for the cartilage, ligaments and muscles to adapt themselves to the normal positions so that the correction becomes permanent.

In infancy under three months, repeated plaster of Paris correction without tenotomy, and in children in arms with tenotomy of the tendo Achillis, and in older children with tenotomy of the tendinous insertion of the tibials, plantar fascia as well, enables over-correction of the deformity. This over-correction should be maintained for several months, and should be followed by some apparatus to ensure normal walking, for in young children a turn in gait leads necessarily to relapse.

Proper walking braces worn inside the shoe, holding the foot in an exaggerated valgus position are often needed. On the sole of the boot a high wedge pressing up the cuboid will correct intoeing in walking if the varus has been fully corrected.

In resistant cases it is sometimes necessary to remove a wedge-shaped piece of bone from the neck of the os calcis and of the astragalus, sparing the articulation to secure proper overcorrection. It is especially important that the cuboid be placed in a normal position, otherwise relapse is sure to follow even if apparent correction has taken place. A club-foot wrench will be found of great assistance in the more resistant cases.

TORTICOLLIS.

The improvement in the treatment of wry neck, *i. e.*, the deformity due to contraction of the sternomastoid, is the result of the aseptic method in surgery. In the preaseptic days the surgeons dreaded the danger of pus in the deeper fascia and subcutaneous tenotomy was the operative procedure employed to divide the contracted muscle. This division was not easily performed thoroughly on account of the neighboring large vessels. Contracted muscles partially divided do not permit satisfactory results; much was left by the surgeon to after-treatment and heavy appliances were used in these half cured cases. When open incisions became safe cures of torticollis were more readily accomplished. The contracted muscle is to be thoroughly divided, the distortion, forcibly over corrected, the head held in an overcorrected position for three months by a plaster of Paris bandage, or by this followed by a light but efficient correcting appliance. There are several methods for the division of the contracted muscle. The one preferred by the writer is an incision carefully made parallel to the clavicle, a few lines above it, with complete division of the sternal and clavi-

cular insertions, a director having been inserted under the tendon to protect the vessels which lie deeper. It is rarely necessary to divide the scaleni for even when contracted they may be forcibly stretched sufficiently.

A complete permanent cure should result.

CONGENITAL DISLOCATION OF THE HIP.

In the investigation of methods of care of an affection hitherto regarded as incurable, the Children's Hospital has been active for thirty years, from the time of the premature announcement of a cure, afterwards followed by a relapse, by Buckminster Brown by the means of traction applied continuously for a long period, and the first attempt, apparently but not actually successful, by Post of Boston at manipulative reduction. Subsequently the reduction by open incision was performed with a fair percentage of success in a number of cases. Hoffa, of Berlin, operating upon one, and later the method of manual forcible reduction, the Paci Lorenz method, was employed, (several operations being performed here by Lorenz.) The first thoroughly efficient mechanical appliance for reduction introduced by Mr. Bartlett, was employed in a large number of difficult cases with success and finally a careful study of the pathological anatomy of two children dying of contagious disease, before and after operation, made the pathology of the affection clear and the methods of treatment and their indications precise and definite.

At present it may be said that the deformity is an eminently curable one.

These cases can be divided into two classes: dislocated hips with an open, and with a narrow capsule. Originally in infantile cases, as is shown by pathological specimens, the capsule is open and loose, the head can be easily placed in or pushed out of the acetabulum. The defect consists in the absence or relaxed condition of the cotyloid ligament and zona orbicularis, which even in a full term foetus is strong enough to hold the femoral head in the socket.

After the child has walked upon the limb, as the body weight falls upon the capsular ligaments and not on the bone structure of the socket, the capsular ligaments become altered in shape and structure, the capsule extending to the upward displaced head is stretched across the acetabulum. In the older cases the capsule tissue becomes firm and resistant and the head can not be replaced in the acetabulum but is pressed against the drum-head-like tissue consisting of the capsule stretched across the acetabulum. The replacement consists in forcible widening of the narrowed capsular opening between the head and the acetabulum and stretching any obstacle which may oppose and pushing the femoral head into the bottom of the socket without folding the capsule in front of the head. To avoid the latter, the lower part of the capsule should be put under tension when replacement is attempted and to facilitate the reduction the head should be manipulated so as to press in the lowest portion of the acetabular rim (*i. e.*, behind and at the middle.) Shortened muscles can be stretched or relaxed by placing the limb in a flexed and adducted position. Forcibly abducting the flexed limb with pressure on the trochanter presses the femoral head against the tightened capsule and if favorably placed forces it into the socket.

In the cases with an open loose capsule little or no difficulty is encountered in the reduction; in tough, tense, and distorted capsule some force is needed. When the capsule is too firm and narrow to be entered by force, reduction by incision is necessary as the capsular contraction needs to be divided as in the reduction of an incarcerated hernia.

Reduction by incision is rarely needed in young cases, but in the more resistant cases, the procedure has resulted most satisfactorily. Forcible reduction can ordinarily be performed by manual manipulation under an anaesthesia, but in the more resistant cases, when much force is needed to stretch the capsule contraction, mechanical force is an important aid; first, to hold the pelvis firmly, second, to exert traction to stretch the capsule, and third, to apply forcible pressure, driving the head of the femur through the contracted capsule opening.

After the reduction the head should be held in place for a sufficient time for the capsule to form firmly about the femoral neck, that the head may be held in place. Plaster of Paris fixation for several months after a thorough reduction ordinarily ensures a cure which is permanent, as the Hospital statistics at the Children's Hospital have shown.

COSTUME DEFORMITIES.

The fact that growing bone could be altered in shape by pressure constantly applied was not unknown 40 years ago, but that the slight pressure of clothing could alter the shape of growing children was not realized. As is well known now definite faults in shape can be traced as a result of clothing. Round shoulders, weakened neck muscles, prominent clavicles, hollow chest, result from an overgreat drag upon the shoulders caused by the pull of elastic side garters attached to children's waists. Undue abdominal pressure from tight waists, corsets, weakens the abdominal, back and loin muscles. Growing girls should wear loose garments with no shoulder drag or abdominal constraint.

SHOE DEFORMITIES.

The extent of the deformities of the foot from shoe wearing is not generally realized, but a comparison of the baby's foot and that of an adult who has never worn shoes with the foot

of any individual who has worn even ordinary footwear since infancy will demonstrate the fact that the habitual compression of the foot, even only to the extent of the amount of pressure of what are termed comfortable shoes, causes muscular atrophy and the loss of normal muscular foot power. When "stylish" shoes are worn, compressing the front of the foot, or simply checking its proper spread when full weight and the exertion of the back drive of the foot comes upon it, the foot becomes in time distorted.

The foot placed firmly upon the ground, if a heel is worn on the shoe, tends to slide forward and this tendency is increased in the speed of walking. The front of the shoe is always narrower than the spread foot and the toes are necessarily crowded into this narrower space. The stiffness of the sole prevents normal toe flexion, and the fact that the upper is always fitted snugly to the dorsum of the foot to diminish wrinkling of the leather as the shoe is worn, hampers normal play of the foot and checks toe flexion. The stiff shank adds to the crumpling of the foot, and an unstretchable seam across the dorsum of the foot, pressing with a strong pressure on the dorsum of the foot, checking the sliding of the foot forward at each step, exerts a cramping pressure.

The result is that the foot which, as an implement of locomotion admirably adapted by the varying movement at its different articulations to the different conditions and activities of locomotion, is cramped for the greater part of the day in a firm and partially stiffened box.

The part of the foot which is the first to suffer is what may be termed the thumb action of the 1st metatarsal which is lost early. The flexion clutch of the toes, the spread of the front of the foot, muscular strength of the muscles of the sole of the foot and the adductor and flexor muscles of the toes all are impaired, crowding and crumpling of the smaller toes and hallux valgus, a flattening of the transverse arch are frequently developed and by the friction of shoes, bunions, corns, and exostoses. The development of static pes plano valgus usually known as flat foot is the most common result of shoe deformity and it may range from a slight functional weakness to a fixed deformity.

For the full details of treatment for the correction of these deformities and affections more space is required than can be furnished in this publication. That all these ailments, little understood thirty years ago, are entirely curable is well established. The most important element in treatment and in prevention is the removal or avoidance of the cause, viz., faulty foot wear. This indication is clear when it is known that these affections are not known among moccasin-wearing or bare-footed people, while extremely common among urban people with the more snugly fitting shoes. Young children, when it is not possible for them to be barefooted, should wear as much of the time as is possible moccasins or sandals and at all other times should be furnished with broad toed, loose shoes. Adults, when clumsy shaped, loose shoes are not feasible, should wear as much as possible as a rest to the foot, loose, flexible foot-wear. When walking, or using the feet a great deal, broad toe shoes should be used and conventional shoes only when the feet are not to be used actively.

Measures to strengthen the foot muscles, muscles of the sole and the correction of existing deformity are essential for a cure.

Stiff shoes, flat foot supports are to be regarded as temporary measures to prevent ligament strains. Faulty attitudes in standing and faulty use of the foot in walking are to be avoided by training.

STATIC AND ACQUIRED DEFORMITIES OF THE FEET.

A Children's Hospital does not offer adequate clinical material for a complete study of those acquired deformities of the feet which are more commonly seen in adults than in children. For a thorough understanding of the subject, however, a knowledge of the varieties of human gait and the normal action of the feet is of assistance. This is more readily studied in infants and children than in adults, as continued shoe wearing develops a more or less pathological condition.

An observation of a large number of children's feet shows that in the feet of even comparatively young shoe-wearing children a definite amount of loss of muscular strength is often produced in a majority of cases, together with toe crowding. Toe crumpling may be developed in stocking and shoe wearing children even when not more than three years of age. Investigation has shown that most acquired and static foot deformities (in cases not complicated by trauma, congenital defects or paralysis) are in reality shoe deformities. Investigation has also shown that the normal foot in infancy varies in shape (except as to the length of the second toe) according to race and is true to a type which it would appear has not changed since the prehistoric man.

Although these acquired deformities are much more common in adults than in children, no one can master the subject who has not familiarized himself with the shape and functional activity of the feet, both in shoe-wearing and barefooted children.

TREATMENT OF SCOLIOSIS.

The treatment of scoliosis forty years ago was both unscientific and clumsy to a degree that it could hardly claim a place in the proper domain of rational surgery characterized as it should be by knowledge, judgment, and good sense.

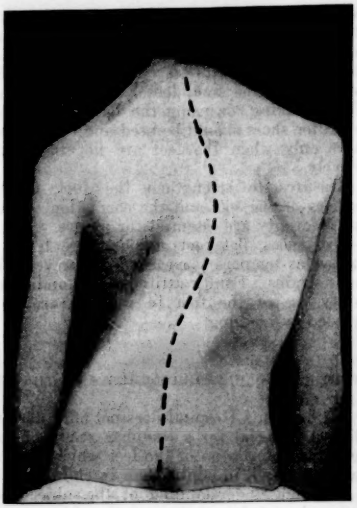

FIG. X.—Resistant lateral curvature in a girl of fourteen before treatment with plaster jackets.

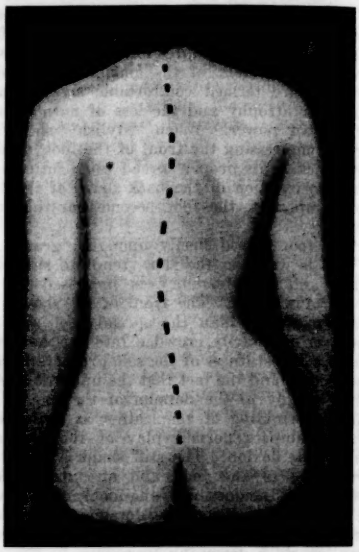

FIG. Y.—Case of scoliosis before application of brace.

The subject was clouded by ignorance as to the true nature of the affection, lack of thoroughness in the methods employed and a lack of definite purpose as to the result sought.

Much satisfactory earnest work has of late been devoted to the subject and it may be added that at present the treatment of scoliosis and spinal curves presents one of the most interesting and satisfactory problems in the field of surgery but one which differs from most surgical questions in that the cure can in no way be hastened by the use of the knife and the course of the affection before a definite cure is established is tediously chronic, involving months and years of observation, beside such time as is necessary for treatment. The affection being a vice in growth, a tendency to relapse exists in many cases during growing years and these years the spine may assume different degrees of variations of distortions according to the amount of resistance of the patient and the varying determining conditions. The resulting spinal curves may be classed as those presented by the weak backs, the curved backs and the twisted backs. The former is characterized by a constant drooping of the spinal column with exaggerated physiological or abnormal curves, which may be voluntarily corrected by the patient, with a tendency to relapse if the patient is tired or remains for any length of time in a sitting or standing position. In the curved backs this condition is complicated by some structural change in the tissue to such a degree that the patient cannot by voluntary effort correct the abnormal curve although in the milder cases these curves can be straightened by pressure of the surgeon's hands.

In the twisted backs the curves are complicated by a twist of the column due partly to the rotation of the individual vertebrae because the superimposed weight forces the vertebrae to twist to the side, as the spine is twisted sideways and partly because the strained ligaments become stretched and offer less resistance to the superimposed weights in one direction than in another, and partly because the muscles pulling on the ribs, the patient being in a curved attitude, twist the column abnormally.

The treatment must necessarily vary according to varying circumstances. Formerly, as it was difficult to control conditions for a sufficient length of time, the satisfactory results were not obtained and many surgeons frankly relegated treatment to gymnastic teachers as the only practical method to be advised.

As the conditions developing these deformities are constantly in the erect position, and as gymnastic exercise could only be practiced for a limited period, the benefit to be derived from gymnastics treatment was limited to the milder cases perhaps capable of improvement under better health conditions or freedom from constricting clothing or faulty school seating.

A step in the study of the disease, was a more rational comprehension of the pathology of the curves and twists. When it became clear that the curves result from changes in a spinal column unable to bear the body weight without yielding with the structural changes resulting

from this inability due to lack of general muscular tone or local weakness and lack of resistance of tissue, a more definite system of treatment became possible. The introduction of plaster jackets did away with the belief that treatment necessarily consisted in general spinal couches and heavy steel corsets, and induced energetic surgeons to turn their attention to the subject of correcting the distorted trunks. But before determining the best method of applying mechanical means to untwist the spine, it was necessary to demonstrate that a pressure upon the projecting ribs acted not simply on the costo-vertebral articulation but the vertebrae itself so that if the pressure were properly applied it could tend to correct an abnormal twist. This has been clearly proved by Dr. Soutter and Dr. Keene.

The effects of abnormal muscle and fascia pull has been carefully studied. Experiments in Germany and here have demonstrated that spinal curves could be developed in growing puppies if fixed for a few months by plaster of Paris bandages in a twisted position. Experiments here also showed the effect of superimposed weight in developing a spinal twist with vertebral rotation and rib prominence. The pathological changes in bones of curved spines has been thoroughly studied. Much study has also been devoted to the normal movement of the spinal column with the result that the informed surgeon is in a position to apply principles deduced from a series of well observed facts to the rational treatment of cases of spinal curve.

Whatever different theories may be presented as to the best methods in treating lateral curvature, all will agree that the whole treatment of structural scoliosis does not consist of or end in the correction of the curve.

Many surgeons have suffered the disappointment of finding a relapsed deformity after a complete correction or over-correction of congenital equinovarus and the probability of recurrence in a corrected curve and twist is even greater in lateral curves than in corrected deformities of the foot, for it is more easy to control the deforming conditions in the latter than in the former class of distortions.

Spinal curves dependent upon vices of growth due to static causes, faulty weight distribution, distorted muscular, or anatomical defect, will tend to recur during the growing years, until the tissues have gained in strength of structure sufficient firmness to prevent yielding to the ever-present force of superimposed weight.

There should therefore not only be vigilance in the inspection of such cases with accurate methods of recording observations at stated times, enabling the surgeon to recognize a threatened relapse, but also measures for the counteraction of such a tendency in an early and more manageable stage.

To apply corrective jackets for a few months or a few years, remove these and leave the patient to take chances of future normal growth, with only as protection from relapse a reliance upon occasional gymnastics and waist bindings, removable braces or jackets, can not be regarded as thoroughly scientific surgery.

Of the various ways of recording scoliosis, there are advantages in selecting one which can be accurately and quickly made, requiring no more skill than that furnished by an office attendant.

The glass plate tracing method offers the advantages of simplicity and accuracy, and can be obtained if a proper diopter is used, and the patient suitably fixed.

A transparent celluloid sheet set in a frame has the advantage of lightness over the glass plate; an ordinary, four post iron piping frame with side pelvis clamps furnished fixation with an inexpensive apparatus. An inexpensive diopter can be made by using a small wooden block, properly squared and of a size to be held in the hand, with a piece of tubing attached at one end. The surgeon looking through the tube of the diopter placed upon the upright transparent celluloid plate, close to which the patient's bared back rests, can carefully follow lines and contours without the error of change in the position of the eye, from a line vertical to the plane of record. If a pencil which can mark on glass is so placed in the block of the diopter that its marking point would strike the recording plate in the center of the inspection tube, an accurate record can be traced on the celluloid plate, from which it can be traced on tracing paper, and kept as a permanent record of contour lines of shoulder hips, the position of the points of the scapulae, and the line of the marked spines. A record of flexibility can be made if the patient with the shoulders are kept flat to the plate and the body bent sideways to either side, and the line of the marked spines traced.

The value of this flexibility test is greater than might at first be supposed.

An examination of a number of these indicates considerable variations in the flexibility of different parts of the column and enables the surgeon to determine the local increase or diminution of spinal flexibility under exercising treatment and hence beginning relapse, and the urgency of a need for the employment of measures to prevent stiffening at any special part of the spine.

Antero posterio curves need for this record a special means of tracing, for diopter tracing fails on account of the projection of the scapulae. This is obviated by using for the tracing of the back the method recommended by Wollenburg, by which the shape of the trunk as seen from the side can be noted.

The accuracy of these tracings by diopter has been abundantly demonstrated as well as the ease with which they can be taken.

It would appear that this method of testing the lateral flexibility of the spinal column is of use, enabling the surgeon to determine func-

tional defects in the spinal column not recognizable by the unaided eye, by the X-ray, or by photograph. An examination of a number of these records show a marked difference in lateral spinal mobility, which when not due to changes in bone structure, as is probable in many cases, though recognized with difficulty, indicates structural changes in the ligamentous and muscular tissue in different parts of the column, changes which can, in favorable cases, be overcome by treatment.

For recording rotation, various methods are offered for the surgeon's selection. The angle record, indicated in the accompanying illustration, is simple and the angle of rotation more easily noted than in the one more commonly used.

Photographs, pantagraphic records of cross sections of the thorax, are all of assistance, but the method mentioned has been found simpler and of satisfactory accuracy.

A record of the strength can be simply made without the employment of elaborate strength test apparatus. A record is kept of the number of times certain prescribed exercises (using dumb-bells of a certain weight) can be performed. This record can serve as a table and an index of increasing strength; multiplying the weight of the dumb-bell by the number of the exercising movements, a strength index can be noted. The exercises to be noted in such a record will vary with the spinal curve, and its muscular weakness. Recumbent dumb-bell exercises, using the movements frequently prescribed for the correction of scoliosis, will serve as a basis for a strength record as well as for systematic muscular development needed in the after-treatment of lateral curves.

The great difficulty in rational treatment encountered in cases of structural scoliosis,—is in the application of such means, as, after correction of the deformity, will prevent the assumption by the patient of faulty attitudes, without at the same time causing muscular weakness of the trunk muscles, and without being so unsightly or cumbersome as to prevent constant use for the long period needed in growing children. A rigid leather or celluloid jacket, or the ordinary back brace does not meet the complex stature conditions involved in faulty attitudes, where the surgeon with a moderate pressure of his hand can rectify a deformity, and yet hesitates to encase the trunk in a stiff corset binding the waist, necessarily weakening the muscles and inefficient in correcting rotation.

This difficulty is usually side stepped, the surgeon prescribing daily exercises, relying upon these for preventing relapse.

Exercises, however, can only be rigidly enforced for a comparatively short period each day, while the need of measures to counteract the static influences causing relapse, is in many instances constant when the patient is erect.

Various appliances have been devised, and none are entirely satisfactory,—an indication that the subject needs further investigation.

FIG. M.—Brace applied.

FIG. N.—Brace applied. Front view.

It is manifest that there is need of pressure and counterpressure in various directions, and that this pressure be as effective as possible it should be applied exactly where the curve extends toward the upper part of the spinal column. It is mechanically absurd to apply

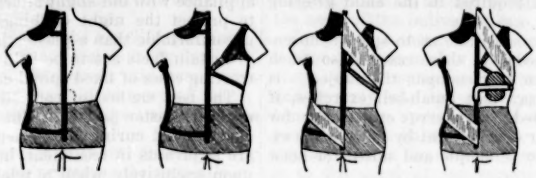

Fig. O.—Diagram illustrating check brace. 1. Showing steel upright side, crutch pelvic, and neck leather. 2. Same with shoulder strap. 3. Same with side correcting bands. 4. Same with rotation pressure pad.

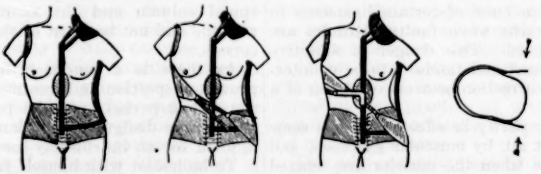

Fig. P.—Diagram of brace as seen in front with out-line showing points for rotation correction.

correcting pressure only or chiefly on the lower part of the trunk and where the column twists and it is desirous to check this. Any corset which twists with or around the trunk is inefficient.

It is better to frankly leave the patient to the correcting forces of nature than to use inefficient measures, which cause discomfort and even injure. But if the surgeon leaves scoliotic curves to chance, he must expect relapses in many cases.

It is of the first importance in a reliable check brace, meaning by this an appliance which will check a slump to faulty attitudes, that it should fit the pelvis at the hips, in order that it should not twist. This can be satisfactorily furnished if a cast is taken, and leather is stretched around such a cast. A base for counter-pressure, both lateral and diagonal, is in this way furnished, and the tendency to slip around the trunk checked.

A leather collar can be moulded at the neck for the upper point of counter-pressure, extending down to the shoulder, but, as this has a tendency to project with the patient's movement, it is better to rely upon a strap for counter-pressure, where it is important to avoid unsightliness or a conspicuous brace. A steel rod connecting the upper and the lower points of counter-pressure serves to furnish a line for lateral pressure. This should be secured to a cross-band attached to the leather around the pelvis, and should be stiff enough not to twist.

A light steel crutch, reaching from the pelvis to the axilla on one side, prevents the riding upward of the brace, and checks the patient's tendency to drop a shoulder.

Points for counter-pressure being furnished at the neck and pelvis, side correcting pressure is needed upon the ribs at the region of greatest deformity. This can be arranged by a broad strap fastened to the steel upright at a desired point; can if secured by a strap to the pelvis leather be made to exert any desired amount of counter-pressure.

Where one shoulder is held high with projection of the scapulae, this can be checked by means of a shoulder strap, which passing around the back uprights is secured in front, pulling the shoulder back and down.

In front the neck and the pelvis leather should also be connected by a steel upright to give steadiness, and, if furnished with a leather pad, can be made to exert pressure upon the front projecting ribs.

In a majority of such cases, it is also necessary to check rotation of the ribs. This must be done by pressure, exerted in such a way that it will not also compress the flattened parts of the chest.

Cross steel straps attached to the uprights and furnished with pads can be arranged like a clamp to press upon the projecting ribs without crowding the depressed portion of the trunk.

An appliance of this character needs careful adjustment at first, but can be regulated by the patient or nurse, and does not interfere with activity, and is not noticeably disfiguring. It will prevent the patient's tendency to slump into a faulty attitude. As it is removable, it can be worn only for such a portion of the day as is necessary to correct the greatest tendency to slump, or it can be used constantly, removed only during the gymnastic period. It furnished the maximum amount of pressure with the minimum amount of injurious muscular constriction.

As there is comparatively little objection on the part of the patient to a light apparatus of this character, correction can be employed as

long as may be required in the child growing period.

Little need be said here as to special muscular exercises needed in these cases as so much has already been written upon the subject. It is sufficient to say that bumb-bell exercises, if properly directed, can serve excellently for special muscular development by daily home exercises; they can be simple and suited for home direction.

Something more than muscular exercises and check braces are needed in the more obstinate of these cases.

A constant tendency of certain ligaments to lose elasticity exists when faulty attitudes are constantly assumed. This danger of adaptive change in ligament and fascia is to be counteracted by daily correction or over-correction of a faulty curve.

This can only partly be effected, and in some instances not at all, by muscular exercises, and should be made when the muscles are relaxed in order to overcome muscular resistance. Correction of this sort must be accurately applied, and should be of such a character that it may be made a part of the daily home routine.

An arrangement indicated in the accompanying illustration will be found to have certain advantages for home correcting exercises.

It consists of an oblong piping frame with cross cloth straps for head, shoulder and pelvic rests for the patient, who kneels head downward in the frame; side straps with weight pulls to keep pelvis and trunk in a correcting direction, and by means of a lever with pressure attachment the twisted thorax can be over-corrected at any desired section. The amount of correcting pressure can be easily regulated.

This arrangement for daily correction can be used also in the application of corrective plaster jackets, and it will be found of advantage for this purpose in many cases, especially in the higher curves.

The avoidance of conditions favoring faulty attitudes is advisable in the after treatment of spinal curves, corrected, or in the earlier stage of development.

The avoidance of sitting for long periods without the interruption of a period of active play, the enforcement of a period of flat recumbency or the prone position to rest the back muscles, serve as an aid to prevent a habit of faulty attitudes. Lounging in large, or deep, or broad seated chairs, is to be avoided, as it favors a twisted attitude. Expensive, especially made chairs, are not necessary. A narrow seated stool or chair with proper attention to the length of the legs can answer for study or any occupation requiring a seated position for some time.

Night corrective appliances are as a rule not necessary for cases of structural scoliosis after the stage of plaster-of-Paris correction, nor in the slighter flexible cases. If this is not the case, the appliances mentioned can be worn as a night appliance with but slight alteration and padding to protect the night clothing. It is not more uncomfortable than a plaster jacket.

Certain facts are to be held in mind by those treating cases of fixed spinal curves.

The best method of correction is by properly applied plaster jackets. But correction of the curve is not curing the patient and gymnastics are adjuvants in treatment, but not to be relied upon exclusively when a relapse is threatened.

Check braces are of assistance if they prevent slumping and faulty attitude. Such braces should be efficient and prevent slumping of the spinal column and the assumption of faulty attitude and not be waist or thorax compressing corsets.

As there is a tendency to relapse during growth, inspection and treatment may be needed for a long period. As the patient has rights, ugly, heavy disfiguring appliances should not be applied for an indefinitely long period.

To be honest with himself the surgeon should in watching the most chronic of surgical ailments keep accurate records and measurements of contour, flexibility, curve and rotation to enable him to detect relapse definitely and to note gain positively.

PLASTER OF PARIS JACKET CORRECTION.

Sayre's plaster of Paris jacket proved of unestimable value in the treatment of caries of the spine, but the benefit obtained in scoliosis from head suspension and plaster jackets applied in this position was not so marked; but it has been abundantly demonstrated that a steady pressure correcting and constantly applied will correct curves in scoliosis and that a properly applied plaster jacket furnishes a suitable means for such pressure.

Various methods have been suggested for the suitable application of jackets, and as the curves vary considerably, difficult methods of application will be needed.

Manifestly the maximum of endurable pressure should be exerted upon the convexities in the trunk while no pressure should be placed upon the hollows, which will gradually expand in respiration if freed from pressure while the rest of the chest is compressed.

The best method of application of plaster jackets are those giving the patient the least discomfort, the surgeon the greatest convenience, while placing the patient in such a position that correction will not present unnecessary obstacles, *i. e.*, the patient should be recumbent rather than standing, that the superimposed body weight should be eliminated as a factor. Whether the best position is with the patient upon the back, face or side, depends largely upon the seat of the curve, high dorsal, low dorsal; lumbar; in the higher curves a position upon the face seems preferable and in the lower upon the back, in the higher curves the jacket

should reach above the shoulder on the side of the dropping shoulder.

The writer has found the kneeling position of service, the shoulders and pelvis being fixed with side pressure correcting curves and strong pressure upon the most prominent part of the deformity with counter-pressure arranged as needed.

No difficulty is met with in providing any amount of correcting pressure; the patient's endurance is the limit of feasible application.

Removal jackets are much less effective than permanent ones as means of correction, but they become necessary where the maximum amount of correction has been reached to prevent muscle weakening by daily exercise.

Removable leather jackets exerting constant correcting pressure, and light supporting braces are effective but not disfiguring, and worn for a long time make with proper gymnastics a systematic treatment possible, continued through the growing years if necessary. The nature of the treatment will depend upon the progress of the case which can be determined by careful records. It is to be remembered that while the bones of the spinal column are lacking in resisting structure and bear the superimposed weight of the body and while faulty attitude persists either from an anatomical defect or from habit or muscle weakness, after correction of curves, recurrence must be guarded against.

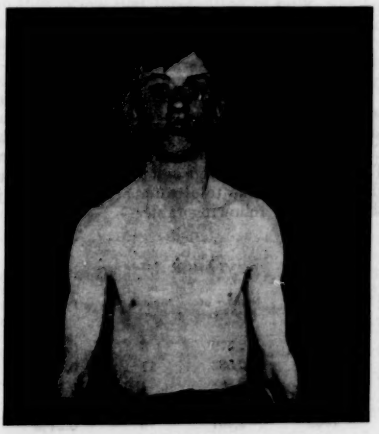
A KNOWLEDGE OF THE USE OF APPARATUS.

An obstacle to the more general study of the special branch known as orthopedic surgery has been the need of readiness and skill in the prescribing and applying suitable apparatus. This is not absolutely necessary in practice.

The surgeon can correct deformities by operative measures or by the use of plaster of Paris bandages, and be entirely independent of the instrument maker. At the same time in a large number of cases better results can be obtained as in other branches of surgery if the orthopedic surgeon is thoroughly familiar with the best implements for the readiest accomplishment of certain desired results.

The first essential in an apparatus is that it should be efficient, *i. e.*, that it should meet the mechanical indications in the most direct and thorough way.

The second requirement is that it should be as comfortable to the patient as possible.



A third, that it should be simple and readily applied by the attendant, nurse, or mother.

Great improvement has in the last 30 years been wrought in the simplification of appliances and at present the experience in our hospital clinic, where the orthopedic appliances used are made under the surgeon's direction, will give the necessary knowledge.

A surgeon, however, who has not mastered the details is as poorly equipped in his art as an artist who has not mastered his palette. The surgeon needs to be able to adapt apparatus to the need of the individual case.

In practice there is a natural tendency at a large clinic to neglect the careful use of appliances, which require some experience and skill, and to rely on the use of plaster of Paris bandages, the application of which are often relegated to a subordinate, or are more easily applied than is the case with apparatus. There is to the mind of the surgeon, as ordinarily trained, a prejudice against the use of apparatus with joints, straps, and buckles. This prejudice is not only unfounded but based largely on the supposition that a knowledge of the use of appliances is something which is with difficulty acquired. Although plaster of Paris bandages have many advantages they are not without marked disadvantages, and no one undertaking the practice of orthopedic surgery should fail to familiarize himself with the careful use of appliances.

The early establishment of a shop in direct connection with the Hospital with workmen under the control of the surgeon proved of great advantage in the treatment of deformed children at the Children's Hospital.

No. 44.—Torticollis, right.

Driscoll, age 5. Date of admission, Aug. 28, 1896. Date of discharge, Sept. 3, 1896. Duration, 3 years. Since birth. Operation, Aug. 28, 1896. Incision, myotomy, plaster. Result 10 years later.

A retrospect like this would be incomplete without a few words as to the probable future of orthopedic surgery as a specialty. It was certainly justified itself in the past by its record of advance in the care and better treatment of a considerable number of affections previously regarded as practically incurable or treated with great difficulty. But the question is pertinent whether in the future the prevention and

cure of deformities will not form a part of the work of the general surgeon. Specialization is to be condemned unless justified by definite reasons; surgery is surgery-healing by means of the skilled hand. But there is a great difference in the skill needed by the operator who attempts to overcome a disease by a surgical feat and that required in the management of cases where special treatment is needed, for months or even years, before, after or in place of an operation. It is doubtful if any surgeon can become a leader in both fields at once. Orthopedic surgery will, it would seem, retain its place as the surgery of chronic cases.

Ambroise Paré is right in his famous saying,—that the surgeon was but a dresser, as healing was in the hand of the Deity; but in correcting deformity, the surgeon must often match his skill against an errant nature, using the laws of growth against the faults of growth.

VI.

INFANTILE SCORBUTUS.

BY JOHN LOVETT MORSE, A.M., M.D.

THERE has been a rapid and progressive increase in the number of cases of scurvy coming to the Medical Out-Patient Department of the Children's Hospital during the last four years. This increase has been not only absolute but also relative to the total number of cases, as is shown by the following table:—

TABLE I.

Year.	Number of New Cases.	Number of Cases of Scurvy.	Percent.
1904	2,579	3	0.11%
1905	2,533	11	0.43%
1906	2,288	4	0.17%
1907	2,075	7	0.33%
1908	2,407	6	0.24%
1909	2,062	5	0.24%
1910	2,311	11	0.47%
1911	1,967	12	0.61%
1912	1,932	13	0.67%
1913	2,416	21	0.87%

An analysis of the foods taken by the babies suffering from scurvy during the last ten years was then undertaken to determine, if possible, the cause of this increase. The data in the records were, unfortunately, in many instances, incomplete. The food taken by these babies at the time of the appearance of the first symptoms of scurvy is shown in the following table. No data as to the food was given in the others.

TABLE II.

Condensed milk mixed with water or gruel	4
Proprietary foods mixed with water	14
Proprietary foods mixed with milk—raw	1
pasteurized	1
boiled	7
no data as to heating	7
Proprietary foods, no data as to milk or heating	10
Milk, plain, diluted with water or cereal diluents, or modified—pasteurized	5
boiled or scalded	23
no data as to heating	14
Breast-fed	3
Total	89

A summary of the above figures shows that 18, or 20%, were fed on "stale" foods, that is, condensed milk or proprietary foods mixed with water. 44, or 50%, were fed on either proprietary foods or condensed milk. In the 37 cases in which milk was used either with or without proprietary foods and data given as to whether it was heated or not, the mixture was given raw in one, or 3%; pasteurized in six, or 16%; boiled, scalded or sterilized in 30, or 81%. It is probable that the milk was boiled in at least one-half of the other cases in which milk was used with proprietary foods, because the directions on the can containing the food used in these cases call for boiling. It is also probable that in a considerable proportion of the cases on modified milk prepared at milk laboratories the mixture was pasteurized.

It would appear from these figures that proprietary foods, "stale" foods and the heating of milk to the temperature of pasteurization or higher, may all play a part in the etiology of scurvy. The fact that three cases developed in babies taking only breast-milk shows, however, not only that no one of these can be the exclusive cause, but also that there must be some other cause. The most striking fact in these figures is, however, that 54 of the 58 cases, or 93%, in which there are data as to the "freshness" of the food, were fed on foods which were not fresh, that is, containing either no milk or cooked milk.

It was thought that a comparison of the feeding of the individual infants in a year at the beginning of the investigation and in the last year might show something as to the cause of the increase in the frequency of the disease. The following table shows the foods taken by these babies in 1905 and 1913.

TABLE III.

1905.

1. Mellin's Food. No data as to milk or heat.
2. Modified milk. No data as to heat.
3. Modified milk. No data as to heat.
4. Malted milk. No data as to milk or heat.
5. Mellin's Food mixed with condensed milk and water.
6. Sterilized milk, shredded wheat, oatmeal, barley.
7. Condensed milk and oatmeal gruel.

8. Malted milk and barley gruel.
9. Malted milk and water.
10. Mellin's Food with milk and water. No data as to heat.
11. Breast.

1913.

1. Modified milk. Boiled.
2. Modified milk. Boiled.
3. Modified milk. Heated. Temperature not given.
4. Milk and water. Boiled.
5. Milk. Boiled.
6. Nestle's Food. No data as to milk or heat.
7. Modified milk. No data as to heat.
8. Milk and barley water. Sterilized.
9. Mellin's Food, milk and water. Made with pasteurized milk.
10. Condensed milk.
11. Eskay's Food, milk and water. Boiled.
12. Milk and water. Boiled.
13. Eskay's Food, milk and water. Boiled.
14. Breast.
15. Modified milk. No data as to heat.
16. Milk and water. Boiled.
17. Modified milk. 155° F.
18. Mellin's Food, milk and water. Boiled.
19. Milk and barley water. Mixed hot.
20. Modified milk. Made from pasteurized milk and boiled.
21. Milk and water. Scalded.

It appears from these figures that the proportion of babies fed on the proprietary foods in 1913 was much smaller than in 1905. It hardly seems reasonable, however, to draw the conclusion from this fact that babies fed on milk are more likely to develop scurvy than those fed on the proprietary foods. It seems more reasonable to suppose that something was done to the milk in 1913 that was not done in 1905. It is striking that boiling of the milk was very common in 1913. Unfortunately, the data as to the heating of the milk in 1905 are very incomplete, so that a comparison is impossible. The number of cases is, moreover, too small to justify any conclusion.

The disproportion between the number of cases fed on raw milk and heated milk and the great preponderance of cases fed on heated milk in 1913 suggested strongly that the heating of milk might play an important part in the etiology of scurvy. It also raised the question whether the large number of cases on heated milk in 1913 was simply a coincidence or whether there was some general factor of heating present in 1913 and not existent in 1905. It was thought that such a factor might be found in the more general pasteurization of the milk supply of Boston in recent years. There has been a rapid increase in the amount of pasteurized milk used in Boston during the last few years, as is shown by the following table:—

TABLE IV.

Year.	Percentage of Milk Pasteurized.	
1908	33.58	
1909	30.68	Approximate; probably too low.
1910	63.50	
1911	73.02	
1912	70.59	Approximate; probably too low.
1913	80.00	Estimated.

A comparison of the percentage of milk pasteurized in Boston and of the percentage of cases of scurvy to the total number of cases coming to the Medical Department of the Children's Hospital during the last ten years is instructive and suggestive.

TABLE V.

Year.	Percentage of Cases.	Percentage of Pasteurized Milk.
1904	0.11	
1905	0.43	
1906	0.17	
1907	0.33	
1908	0.24	33.58
1909	0.24	30.68
1910	0.47	63.50
1911	0.61	73.02
1912	0.67	70.59
1913	0.87	80.00

The figures given in this table do not, of course, prove positively that there really has been an increase in the number of cases of scurvy in the community during recent years or that, if there has been such an increase, it is due to the introduction and progressive increase of the commercial pasteurization of milk. Neither do they prove that the heating of milk, whether to the temperature of pasteurization or boiling, has anything to do with the etiology of scurvy. They do suggest, however, that there may be some such connection and justify further study of the subject on a larger scale.

Symptomatology. An analysis of the symptomatology of these cases was undertaken, but was not very satisfactory because of the meagerness of the records in many instances. The results of this analysis are given, however, for what they are worth.

The first symptom noted was:

Crying on handling	69
Paresis	11
Swelling of legs	5
Abnormality of gums	2
Ecchymoses	1
Bloody urine	2
"Failing"	1
Condition discovered at Hospital	2
Total	93

The following symptoms were noted at the examination, or were given in the history of the patient. They are undoubtedly incomplete, but presumably show something as to the relative frequency of the different symptoms.

Tenderness of the legs and crying on being handled	93
Swelling of legs (thighs 10, lower legs, 15)	25
Swelling of the arms	3
Loss of power in legs	20
Rigidity of legs	15
Inflammation of gums	37
Discoloration of urine or staining of diapers	6
Swelling of eyelids	1
Ecchymosis of eyelids	1
Ecchymoses	9

Errors in Diagnosis. The diagnosis of inflammation of the joints had been made in one of these cases, of fracture of the thigh in another, and of tuberculosis of the spine in still another. These figures do not give a correct impression, however, as to the frequency with which this disease is overlooked or mistaken for some other condition. This disease was recognized by the attending physician in but four of thirty-seven cases seen by the writer in consultation or at his office in the last five years. It was overlooked entirely in twelve, while the following diagnoses were made in the other cases:—

Rickets	1
Rheumatism	4
Injury to spine	1
Disease of spine	1
Diphtheritic paralysis	1
Infantile paralysis	3
Acute nephritis	5
Tuberculosis	1
Teething	1
Injury to leg	2
Inguinal hernia	1

It is evident, therefore, that in spite of all that has been written and said about infantile scorbutus during the past fifteen years, there are still many physicians who are not familiar with the disease or who, if they know of it, are unable to recognize it. A campaign of education is, therefore, necessary, especially in view of the fact that the disease is apparently on the increase.

VII.

INGUINAL HERNIA IN CHILDREN.

BY JAMES S. STONE, M. D.

In the Children's Hospital since the establishment of the Surgical Service, 1019 cases of inguinal hernia have been operated upon.

This paper is based upon a study of these cases; the purpose being to present broad conclusions. Details of cases and details of treatment are given solely with the purpose of making the conclusions clear and of emphasizing points more commonly seen in children than in adults.

Etiology. It is today generally recognized that certainly in children the existence from birth of a patent sac is the common cause of hernia. The evidence of this congenital origin of inguinal hernia rests mainly upon the anatomical conditions which are practically invariably present. The structures of the cord, the vas and vessels, lie spread out upon the posterior surface of the sac and most intimately connected with it. In girls the anatomical conditions are practically always analogous to those found in boys. The round ligaments and the vessels lie spread out upon the posterior surface of the hernial sac.

The frequency with which a small hernial sac is found in association with a hydrocele of the cord is also evidence of the congenital origin of hernia. Instead of a sac patent from the peritoneal cavity to the tip there has been an obliteration of the sac at one or more spots. Very frequently indeed there is at one or more places in the sac a partial obliteration with the formation of a fibrous ring, often very adherent to the surrounding structures of the cord. Such conditions could not possibly be produced by the pushing out of a sac by any intra-abdominal force.

Confirmatory evidence of the congenital origin of hernia is found in other facts.

First. A very large majority of all cases occur on the right side. The left testis descends first and farther than the right. Thus there is a longer time and better opportunity for obliteration of the funicular process on the left. The patent sac is more common on the right.

Second. The sudden appearance of a hernia without adequate cause unless there existed a sac ready to receive the hernia. This condition is very common in both children and adults.

Third. The readiness with which a hernia at times develops the moment that for any reason fluid accumulates in the peritoneal cavity, while in other cases fluid can be present for months without the development of a hernia. In the one instance the fluid finds its way into and distends an existing sac. In the other instance the pressure of the fluid is not sufficient, although acting like a hydraulic press, to cause any yielding of the canal.

Fourth. The finding at autopsy or at operation for other conditions of a patent but empty sac.

If hernia is due to the existence from birth of a patent sac, the obvious question is why does the sac frequently remain empty so long. It may be so for months or years, even to adult life. In order to have anything enter the sac three conditions must exist simultaneously. First, there must be a relaxation of the muscles which naturally guard the entrance to the sac. Second, the other muscles of the abdomen must be tense in order to push anything into the sac. In the third place there must be something opposite the entrance to the sac able to pass into it.

It is most unusual to have some of the abdominal muscles tense and others relaxed. Hence the first two conditions seldom coexist. The third condition is more readily obtained, but is still important. A distended loop of bowel would not enter the sac readily. Neither would a flat portion of the omentum. A tab of omentum might easily enter. Fluid always enters readily. Much of the intestine has a mesentery

so short as to prevent it from entering a hernial sac.

Though almost all cases of hernia in children are due to the existence from birth of a patent sac it seems probable that other factors must be recognized, which apply both to children and adults. In infantile atrophy and frequently in old age there is an absorption of the fat which normally fills up the inter-spaces between the surrounding muscles and the tissues passing through the inguinal canal. There is at the same time an associated weakening of all the muscles, including those which guard the entrance to the inguinal canal. Any straining will under these conditions gradually push down a hernia. A hernia may occasionally be seen to develop in an atrophic baby, and the same thing may be seen in old age. The loss of the fat has given a point of vantage for the development of a hernia.

There remain some cases in which a hernia may develop gradually in strong individuals as a result of hard muscular work; the yielding of a weak point. There have been no cases seen in children in which this seems probable. It may explain the frequency with which men lifting and handling heavy and bulky objects have hernia.

In reviewing the histories of patients no special diseases seem to have any influence in causing hernia.

Diagnosis. In adults the existence of the tumor is the usual basis for the diagnosis. When not present the impulse on coughing, especially when the finger is inserted within the inguinal canal by invaginating the scrotum, is the common basis for diagnosis.

In children conditions are wholly different. Often the tumor makes the diagnosis perfectly obvious. Frequently, however, the mother has seen a tumor which at the time of examination is not present. In making the diagnosis of hernia one must first make sure that the testes have descended. If they are normal and the hernia is not down the diagnosis then must rest absolutely on the detection of the hernial sac. If it is present there is a potential hernia, and presumably the tumor noticed by the mother was a hernia.

In children little can be learned by invaginating the scrotum to get the finger into the canal. The testis frequently retracts above the finger. The canal is usually small unless the hernia has descended frequently and thus stretched it. The presence of the sac is to be determined by touch. On each side the structures of the cord are to be felt; the vas and the vessels. On each side they are ordinarily of approximately the same size. In cases of hernia the empty sac must be felt. The sac adds little to the size of the cord, but materially alters the feeling of the cord.

If the middle finger is held flat directly over the external ring parallel with Poupart's ligament, and the skin is then gently slid from side to side toward Poupart's ligament and away from it, the cord, including the vas and vessels, and the structures which enclose them, may readily be felt rolling under the finger. If there is no hernia the cords feel alike on each side. If there is a hernia on either side the sac is to be felt in addition to the cord. The feel of the sac rolling under the finger is to be compared to that of a small thin wet rubber finger cot. Something smooth and slippery rolls under the finger in addition to the vas and the vessels. The feel of the mass of veins of the cord is somewhat similar to that of the sac, but practice readily enables one to differentiate the two. One should feel in this way for the sac with the patient standing in case it cannot be felt while lying down. Standing frequently allows a little fluid to enter and distend the sac. In trying to feel the sac in this way the position of the finger held constantly flat against the abdominal wall is important.

Differential Diagnosis. In adults variocele and hydrocele are the tumors which must be differentiated from hernia. In children variocele is almost unknown. In one case the diagnosis of variocele was made. The mass was an adherent omental hernia. Variocele may follow a too tight operative closure of the canal. Hydrocele of the tunica vaginalis is not at all uncommon in infancy. It often exists at birth, frequently disappearing within a few months without special treatment. There is no reason for a mistake in diagnosis. As in adults the tumor is translucent. It is painless unless due to injury or infection or unless the tension is extreme. But the essential diagnostic feature is the absence of any direct connection other than the normal cord between the swelling in the scrotum and the peritoneal cavity. Encysted hydrocele of the cord is, however, very common indeed in children. It is in differentiating hydrocele of the cord from hernia that the greatest difficulty arises. While the difference is often of relatively slight practical importance, yet mistakes made are often very annoying.

Hydrocele of the cord may be unilocular or multilocular. It is usually associated with a hernial sac, frequently very small. The more carefully the cases are observed, both clinically and at operation, the more often does one find that the hydroceles are multilocular and that there exists also a hernial sac.

The most reliable means of distinguishing hydrocele of the cord is the ability to grasp it and move it up and down and from side to side without the restraint which would be inevitable were there anything beside the cord and vessels which connected the mass with the abdominal cavity.

A hydrocele of the cord which has retracted within the canal cannot be differentiated from a hernia unless it is drawn downward suffici-

ently to get a finger above it and find no abnormal contents of the canal.

There have been a few instances of suppurating hydroceles of the cord. The tumor in such cases resembles closely an abscess originating in a lymph node. On the other hand the location of the tumor is distinctly along the inguinal canal rather than just outside it along the course of the lymph nodes. The history of such a tumor is different from that of a bubo. The mass may have been noticed along or outside the inguinal canal for some time, giving no particular trouble until inflamed.

The differentiation between such a mass and a gangrenous strangulated hernia must be made on general grounds. The absence of the intestinal obstruction and of the profound shock which accompany such a hernia are sufficient.

On the other, hand, in these cases there is a distinct danger from the suppurating hydroceles of the cord. Very often the partition between the hydrocele and a hernial sac above it or between the hydrocele and the peritoneal cavity is an extremely thin membrance. The risk under such circumstances from rupture internally and peritonitis is obvious.

It would seem at first sight as though hydrocele of the cord which was suppurating would heal completely if drained and packed. Obviously no other treatment is wise at the time. On the other hand, the hydroceles are often multilocular and often associated with hernial sacs. It is therefore wise as soon as the inflammation has subsided to examine carefully to determine the presence or absence of other hydrocele sacs or of a hernial sac. Then the choice may be made of a radical operation or of waiting for symptoms to arise.

Undescended Testis. In children, especially in those under eight or ten years of age, it is necessary to define exactly what is meant by undescended testis. The extreme mobility of the testes in infancy and early childhood must be recognized.

In a great many instances children are brought for an operation because the mothers, never the fathers, think they are not quite properly developed. In many the testes are of normal size and may be either just within or just outside the external ring. The scrotum is empty. If search for the testis is made from below upward it recedes out of reach within the inguinal canal. In such cases, and whenever there is any doubt, the examiner must always begin by making firm pressure at a point over the inguinal canal just above the external ring. In this manner the testis if in the canal is felt, and if outside the canal is held there by the pressure of the finger so that it may be grasped from below with the other hand. If the testis is felt in the canal it may frequently be pushed downward with the finger and then grasped from below. No testicle which can be drawn or pushed down into the scrotum is to be regarded as undescended. No such testis requires treatment unless under most exceptional circumstances.

Occasionally if extremely retracted the testis may become more or less pinched. Thus there may be sufficient irritation to cause continued spasm of the cremaster muscle and long continued retention of the testis high up toward if not within the inguinal canal. Considerable pain in the inguinal region may result. The testis thus held tight within the canal may become slightly tender. Rest in bed for a few days relieves such a condition. A testis thus strongly retracted may be drawn within the abdomen. In the same manner a normal testis may be pushed back into the abdomen in childhood. In one instance a normal testis so pushed back by the patient never descended again.

Treatment. It has become the rule of the hospital to advise operation in practically every case. Palliative treatment holds back a hernia. It does not effect a cure.

The obliteration or the excision of the hernial sac is the essential factor in a cure. On this fact are based the dangerous and uncertain methods of treatment by the injection of chemical irritants.

In many instances after prolonged use of a truss the hernia does not again appear. But the longer these patients are followed and the more carefully they are studied the fewer become the cases in which one finds that the hernial sac has become obliterated. While the sac remains patent there is always a potential hernia. The risk of such a potential hernia depends upon the proximity to skilled surgical aid in case of need.

As the children are brought to the hospital the practical question which arises is whether there is any contra-indication to operation. If any exists some form of truss is advised. If there is no contra-indication operation is advised. Largely on account of the lack of beds for infants operation is usually performed after the child is two years old. But entirely independent of that consideration unless special reason arises operation is not usually advised until after the babies are weaned and have a good start in life. The risks from operation, slight as they are, seem less in the older children.

Palliative Treatment. In patients waiting for operation or in whom operation is inadvisable the worsted truss is ordinarily advised unless the child is over three years old.

The advantages of the worsted truss are that while almost always efficient it cannot exert injurious pressure. It can be washed. The baby can be put in the bath with the truss on. When the baby is dry and quiet the wet truss may be replaced by a dry one and the one removed may be cleaned and dried for use again.

The method of application is of considerable importance. The skein of yarn is so placed that one end of the loop comes directly over the ex-

ternal ring. The other end is then carried outward around the affected side, brought behind the back above the buttocks and then forward across the abdomen to be passed through the loop placed over the external ring. The free end is then carried under the tuberosity of the ischium of the affected side and brought upward to be tied at a point over the sacro-iliac joint to the skein as it crosses the back. The location at which this tie is made is important. If too far out flexion of the thigh loosens the truss. If too near the median line the worsted slips between the buttocks, irritates the parts and becomes dirty. At the sides the worsted passes above the great trochanter and below the crest of the ilium.

Usually one skein of the white Germantown yarn is used. Less is seldom sufficient. More may be needed in a hernia hard to hold back. A skein may be applied to each side in cases of double hernia.

Operative Technique. The incision, seldom over an inch and a half long and often less, is made parallel with Poupart's ligament, and with the center directly over the upper angle of the external ring. The position of the external ring should always be located by touch just before the cut is made.

The first possibility for error lies in confusing the deep fascia and the aponeurosis of the external oblique muscle. They are always separated by a distinct layer of fat. The fascia, owing to the fat beneath it, is much more readily lifted up with forceps than is the aponeurosis, which is intimately connected with the underlying muscles. After the surface of the external oblique is cleared there is no difficulty in recognizing the external ring—if in no other way, by the intercolumnar fibres running across the upper outer end.

If, however, the incision is a little too near the median line, the hole in the aponeurosis through which the ilio-hypogastric nerve passes is exposed, and if large may be mistaken by an inexperienced operator for the external ring. Thus misled, the search for the sac may be carried down near the lower end of the semilunar line. In one patient whose hernia had not been cured at first, a second operation showed the inguinal canal untouched, while the scar was found in the region mentioned.

The anterior surface of the aponeurosis should be neatly cleaned of fat and cellular tissue. Then the canal is exposed thoroughly by slitting the aponeurosis of the external oblique upward and outward in the line of the fibres as far as the place where the edge of the internal oblique and transversalis muscles spring away from Poupart's ligaments. Care is necessary to avoid cutting the ilio-inguinal nerve, which usually lies directly beneath the line of the incision in front of the cord and its coverings. The nerve is not to be confused with the vas, which practically invariably lies among the vessels on the posterior surface of the sac.

Before more is done the under surface of the split aponeurosis is separated on the inner side from the underlying internal oblique muscle and on the outer side from the cremaster muscle and cellular tissue down to Poupart's ligament. The cremaster muscle lies exposed in the bottom of the wound. It should be seized with two pairs of forceps at the lower central part of the canal and drawn downward and inward. The fibres are thus put upon the stretch, and may readily be split down to the sac or the fibrous tissue surrounding it. Thus the most readily isolated upper middle part of the sac is exposed first.

In dissecting the sac free from the surrounding tissues one should invariably get down to the peritoneum before attempting to separate the surrounding tissues. When the peritoneal layer is reached it has a definite blueish color. If fibrous tissue still remains the color is more white. If the peritoneal layer of the sac is reached the other structures of the cord are readily separated. If dissection with gauze is used great care is necessary not to put any tension on the delicate vas deferens. It may be torn if stretched by careless dissection.

If the dissection is kept close to the peritoneum no blood vessels need be injured. The vas should not be touched directly. Extreme care is necessary to avoid any handling of either testis or epididymis. Ecchymosis or oedema of the scrotum does not occur in cases in which care is taken to keep absolutely to the peritoneal layer in dissecting free the sac.

Swelling of the testis or epididymis does not occur unless these structures or the vas have been roughly handled, or unless gauze or something rough has come in contact with the serous surface of the testis.

The chief hindrance to easy dissection of the sac lies in the frequent occurrence of fibrous rings adherent to the surrounding tissues; places at which there has been a partial closure of the funicular process. The sac is to be freed until it becomes somewhat fibrous in the region of the internal ring, which usually is an imaginary structure, and until the extra peritoneal fat is reached. The empty sac, drawn strongly out, is perforated at the neck, tied in each direction and cut away. The stitch, still attached to the stump of the sac, is then drawn out into view. With this as a guide the needle on the stitch follows the stump of the sac as it is allowed to recede behind the internal oblique and transversalis muscles. The needle is then brought out through these muscles and through the aponeurosis of the external oblique at a point slightly above and to the inner side of the upper end of the slit in the last structure. Thus the puckered peritoneum at the neck of the sac is drawn up behind solid muscle, while smooth peritoneum is stretched across

the region of the canal. The stitch is temporarily laid aside.

Usually three interrupted stitches are then placed to unite the borders of the internal oblique and transversalis muscles to Poupart's ligament. They are all placed in front of the cord. Thus the length and breadth of the canal are decidedly decreased. The angle between Poupart's ligament and the edge of the muscles at the inner side of the canal is frequently wide, especially in a hernia of long standing. This angle is of course at once closed by the operation.

For many years the cord has not been transplanted unless for some special reason. In the Bassini operation, with transfer of the cord and vessels, relapse was rare, but when it did occur it was always at the upper angle of the old inguinal canal, the point at which the cord and vessels were brought forward through the deeper part of the abdominal wall. Those who still transfer the cord usually guard against relapse by passing one stitch above the cord and vessels. They do not carry the lesson taught by relapses to its logical conclusion.

Operative Complications. Certain complications have arisen during operation. In girls with ovaries which have descended into the canal the ovarian vessels must first be separated from the sac, as in an ordinary hernia, and then after excision of the sac the ovary and its vessels must be either sufficiently freed to permit their replacement en masse within the abdomen, or in case the vessels are too intricately connected with the walls of the canal they must be rolled back into the abdomen.

There have been a very few cases in which mesenteric vessels required similar treatment. In one instance a portion of the bladder pushed into the canal. In treating these conditions the object sought has always been a complete removal of the peritoneal sac and a replacement of the other structures uninjured within the abdomen.

One exception has been made to this rule, in a case already repeated in the *Annals of Surgery*. A patient with absolutely normal female external genitalia had an inguinal hernia first on one side and then on the other. On each side a normal testicle was found and removed.

Many cases have been complicated by incomplete descent of the testes. No children have been operated upon in whom the testis had not at least entered the inguinal canal. In general, with incomplete descent of the testis operation has been postponed till well toward puberty, provided the hernia was not giving trouble and provided the position of the testis did not subject it to injury. The object sought by operation has been the separation of enough of the sac to form a tunica vaginalis, the closure of the peritoneum at the neck of the sac, the displacement of the testis downward into the scrotum as far as possible. In securing freedom of the testis it has not been found that the vessels alone were short. Usually all the structures of the cord, including vas and vessels, were deficient.

It is essential for the proper development of the testis that the vascular supply should not be materially injured. The testis should not be roughly handled—if possible it should always be kept covered by peritoneum. Touching the uncovered testis with dry gauze commonly causes much more inflammatory reaction than much squeezing and traction on the protected testis. Retention of the testis in its new position has usually been secured by suture of the tissues about the vas, as it emerges from the abdomen, to Poupart's ligament.

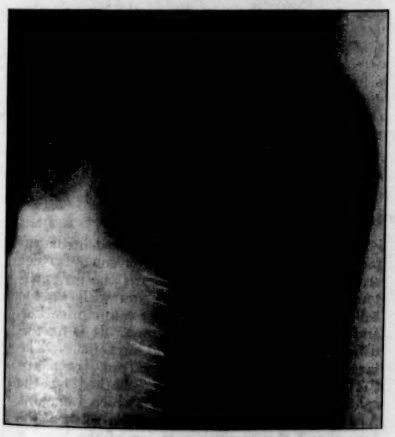
After Care. Various methods of dressing the wound are used according to circumstances. Usually a cocoon made up of a few layers of sterile gauze, is fastened over the wound with flexible collodion. This practically protects the wound from being wet with urine, while at the same time the small amount of gauze is enough to absorb the few drops of blood which may come from the incision. Ordinarily a gauze pad and a spica bandage are applied outside of the collodion dressing. In older children no special precautions are needed to prevent wetting of this dressing. In the younger children various methods to prevent this are used. A thin rubber finger cot may be fastened about the penis with adhesive plaster. The closed end of the cot is slit and fastened to a rubber tube, which conducts away the urine. Of course the cot must be changed before the skin becomes irritated by any urine retained within it.

In some instances the penis may be placed directly in a wide necked bottle tied in place. A piece of thin rubber dam with a small hole cut in it may be placed around the penis. In infants by far the simplest method is that of Stiles—no special dressing. The baby is held on its back by loosely fastening the arms and legs to the sides of the bed. Thus the child is kept from scratching the wound. When a boy passes urine when lying on his back the stream practically always shoots upward and toward the foot of the bed. Any absorbent material stretched below the baby's feet catches the urine. and may be changed as is necessary. The bed clothes must be held up by means of some form of bed cradle.

In girls the dressing may be modified by substituting a pad of absorbent cotton placed between the thighs for the absorbent sheet placed below the feet for boys. In most cases treated in this way a small cocoon is first placed directly over the wound.

In the earlier cases the children were kept in bed for about eighteen days and were discharged at the end of three weeks after operation. Gradually this length of time has been

cut down. At the present time the children are usually kept in bed about ten to twelve days, and are discharged at the end of a fortnight. A spica bandage is usually continued for a fortnight or so after the child is discharged. Some restraint of violent exercise is generally advised for a couple of months after operation.



VIII.

A Case of Chondro-osteo-sarcoma. Amputation at the Hip.

By Robert W. Lovett, M.D.

[From the Orthopedic Clinic of the Children's Hospital.]

C. P., a boy 11½ years old, was admitted to the hospital on February 24, 1913. The family history was good, and the personal history showed measles, pertussis and diphtheria seven and six years previously. There had been no known exposure to tuberculosis. In the fall of 1911, that is, about eighteen months prior to admission, while playing football his right leg had been hurt near the hip. Off and on since then he had limped. He had never had any acute pain, he had eaten and slept well, and there had been no loss of weight. The parents had noticed that the upper part of the right thigh was larger than the left.

Chondro-osteo-sarcoma of Femur.

Physical examination showed that the boy was well developed and nourished, the pupils were equal and reacted to light and distance, the throat was normal, the heart and lungs were normal, the abdomen was soft with no masses or tenderness, the inguinal glands on the right side were enlarged, and a few glands felt in the left inguinal region. Just below and anterior to the right trochanter there was a swelling about three inches in diameter, not reddened but hard and apparently connected with the bone. There was some slight tenderness on pressure over the middle of the tumor. The legs were of equal length, and there was no difference in the circumference of the calves. The thigh was 1¾ inches more in circumference over the tumorous mass than at a corresponding point on the other thigh. There was no distinct limitation of motion of either hip, although the movements in the right hip were perhaps a little less free than those in the other. Examination of the urine showed that it was acid, with little sediment, no albumin, sugar or acetone. Microscopic examination showed no casts, blood, white blood corpuscles, but a few mucous shreds. The von Pirquet skin test was positive, the leucocyte count was 6,500, the Wassermann reaction was negative. The x-ray showed a thickening of the upper

Chondro-osteo-sarcoma.

four inches of the shaft of the femur, and a rounded curve from the neck to the shaft on the outside replaced the normal angle of the trochanter. In the interior of the bone the normal structure was replaced by a somewhat globular homogeneous area both in the cortex and in the medulla. It appeared to be fairly sharply limited, and the suggestion was of a more or less encysted tumor about 2½ inches in length from above downward.

The diagnosis was a troublesome one, and we considered a malignant growth, bone cyst and syphi-

lis. Tuberculosis was suggested by the positive von Pirquet test, but the character of the lesion was not in any way characteristic, and it was regarded as unlikely. The expansion of bone present in this case was not characteristic of bone cysts, and had not existed in those of the same region that I had seen. I therefore regarded that as unlikely. The lesion was also not characteristic of syphilis. The Wassermann test was negative, and the family history negative. Although I felt that no one of these possibilities could be excluded, theoretically I was inclined to the diagnosis of a malignant tumor involving the upper part of the femur. The boy was kept in the ward for study until March 7, when it seemed wise to remove a sufficient amount of the growth for examination in order that the diagnosis might be perfectly sure, because if a malignant tumor existed amputation at the hip joint seemed the only means of cure.

On March 7 I made an incision over the tumor growth, and with a bone gouge removed a piece of bone ¾ inch long and ½ inch thick. Periosteum was sewed over the bone removed, and the operative material sent to Dr. Councilman for examination. Dr. Councilman reported on the 10th of March as follows:

> "The tumor contains some cartilage and small areas of imperfectly formed bone. The general mass is composed of spindle cells. Nuclear figures indicative of rapid growth are few. The cells are few and compactly welded. The tumor seems to originate from periosteum. It is undoubtedly malignant, but whether it has reached the stage of generalization cannot be said."

The boy made a perfectly good recovery from the operation of March 7, and the parents were advised that amputation at the hip joint seemed to be the only treatment worth pursuing. They accepted the situation, and on March 13, 1913, the boy was etherized by Dr. Freeman Allen, who was good enough to serve on account of the character of the operation. Dr. James S. Stone was also good enough to assist me in the amputation. The Wyeth skewers were passed to hold the tourniquet, and there was very little bleeding during the operation. The only difficulty was that on account of the possible involvement of the skin on the outer surface of the femur where I had made the exploratory operation, I was anxious to remove all that material, and, to do this it was necessary to do most of the work at the inside of the femur, leaving the outer surface as far as possible intact and using the inner flap, consequently the dissection was carried on on the inside of the femur and the head disarticulated from the inside, thus removing the tissue positively infected with the tumor.

The patient suffered little or no shock, and had little temperature reaction. The father was told that the specimen carefully examined might be of use, and requested that it should be done. It was therefore sent to Dr. Councilman for examination, who reported on March 17, 1913, as follows:

> "I enclose you a photograph of the cross section of the upper third of the femur which you sent. As you see, the bone is greatly enlarged, and the interior of the bone is filled with a tumor mass that extends up toward the head of the bone at the line just beneath the epiphysis, which I have marked out in ink. Beyond that line the bone seems to be normal. I have also examined a section of the bone taken from the lower part of the medulla (at a point about six inches below the trochanter). I did not go lower down. The whole bone between the two ink lines on the photograph is to a greater or less extent infiltrated by the tumor. On the outer aspect of the thigh the entire bone is involved out to the edge of the periosteum, which you see is somewhat elevated. The pale, homogeneous masses in the centre are chiefly composed of cartilage in which there is some hemorrhage. I do not see what you could have done save amputate as you did. I think that the tumor started in the medulla of the bone in the cartilage, that it is essentially a chrondo-osteosarcoma, and it did not start from the periosteum, which is elevated and involved secondarily. There would have been, as you see, no question of shelling out the tumor or doing anything more than you did. I do not think that there is any probability of there being now or at any time in the future a metastasis from this tumor."

Chondro-osteo-sarcoma.

On April 9, 1913, Dr. Councilman wrote me again with regard to the case as follows:

> "I have been a good deal interested in the tumor of the leg, and I send you some further studies upon it. Figure 1 shows the myxomatous part of the tumor. As you will see, the cells are typically stellate, inter-communicating, and lie in a homogeneous stroma. It is an unusually fine specimen of the myxoma. The large specimen, No. 2, comes from the sharp limit of the tumor which is marked on the colored photograph of the thigh which I enclose. As you will see, the line of junction between the tumor and the cancerous tissue of the bone is perfectly sharp. The tumor is marked on the photograph 1, the normal bone 2. It is very interesting to see that the tumor here is not as sharp as it seems to be. You will notice a little island in the midst of the marrow, which is marked 3. This denotes an extension of the tumor, showing as a small island in the marrow.

You will also note on the edge of the tumor the gradual replacement of the marrow tissue. The tumor, as I conceive it, started mainly as an enchondroma, but with elements of the connective tissues superadded. This was probably congenital. As it began to grow, elements other than the cartilage gained the upper hand, and it became essentially myxoma fibroma. In the growth of this tissue both bone and cartilage disappeared. The large photograph (3) is a very low power through a portion of the cartilage and the bone. The very black masses in the upper portion of the specimen marked 1 show the remains of the bone

Chondro-osteo-sarcoma. Right Femur.

which is being absorbed, with the tumor tissue in between. The lower portion of the specimen marked 2 shows the cartilage undergoing the same sort of absorption. The specimen marked 4 is from the shaft of the bone, and it shows the growing tumor, and the bone absorption. The pale areas here represent the bone, and about these you find growing tissue of the tumor, and along the edges of the bone the absorbing giant cells or osteoclasts. The specimen 5 shows the same thing happening at the edge of the cartilage. The homogeneous areas in this represent the cartilage, which is at this point almost entirely replaced by the growing tissue. I think that your operation was a timely one, and there should be no return of metastasis from tumor, although the single point which I have called your attention to in the marrow renders this just a little doubtful."

The boy remained in the hospital until April 10, 1913, making perfectly good progress. There had been a certain amount of fat necrosis in the flap, but union occurred perfectly well, and when he was discharged there was a slight area about the size of the thumb nail which was granulating. His general condition was excellent, and he was discharged home.

IX.

Obstetrical Paralysis with Especial Reference to Treatment.

By John Jenks Thomas, A.M., M.D.

A little over eight years ago there was published in the Boston Medical and Surgical Journal an article written by me in which I reported two cases of bilateral paralysis of the lower-arm type resulting from injuries at birth. It is not my intention to say anything further at this time in regard to this rather rare form of obstetrical paralysis in the child, of which in twenty years' work at the Children's Hospital I have not seen more than a dozen cases, but I wish simply to allude to the conclusion then stated in regard to the etiology of these birth injuries of the child. As I then stated, the weight of opinion of the more recent writers, Fieux, Duval and Guillain, Schoemaker, Stolper, and Walton, and Stone here in Boston, was inclined to the view that the injury is due to stretching of the plexus in head presentations from the shoulder at the pubes being held back. Confirmation of this theory is also obtained by what has been found at operation in these cases, as in the cases reported in the excellent article of Clark, Prout and Taylor, published after my former paper was written. Dr. Stone, who has kindly operated on some of my cases, once found the plexus entirely lost in a mass of scar tissue lying at Erb's point, so that the nerve resection which we had planned had to be given up as the gap was too great to be bridged.

We may assume then that the paralyses of one arm occurring in infants during delivery are due to injuries of the plexus from stretching. In severe cases hemorrhage takes place about the plexus, or the plexus may at times be ruptured, while in milder cases there is a hemorrhage within the connective tissue sheath of the cord of the plexus with the resulting fusiform fibrous swellings described by Clark, Prout and Taylor, while probably in the mildest cases we have merely a stretching of the nerve bundle with consequent exudation within the sheath. A case illustrating this was one sent to me about nine years ago by Dr. Hunting of Quincy, where a boy of fourteen at a summer camp for boys was punished for some infraction of the rules by being made to carry a number of buckets of wet sand, which he did by placing the bucket on his shoulder, thus press-

ing the shoulder down and the head to one side, and producing a paralysis of the obstetrical type. That the severity of the injury varies in some such way as I have suggested is indicated by the varying severity and duration of the symptoms. No doubt many of the cases where the arm hangs limp by the side recover within a period of time in the neighborhood of a couple of months. If this were not so we should hardly have such varying ideas as to the seriousness of such birth injuries as we find among physicians. As a rule, I think general practitioners and obstetricians regard these cases as quickly curable. The neurologist and orthopedic surgeon to whom the severer cases come later for treatment, on the other hand, probably regard them too seriously, as extremely obstinate paralyses for which little can be done. The pediatrician probably occupies a position about midway between these two extremes.

The grouping of the muscles affected in this form of paralysis is well known as they are the muscles represented in the plexus at Erb's point, where the fifth and sixth cervical nerve roots unite to form the upper cord of the plexus, just before the supra-scapular nerve is given off. These comprise the deltoid, supra- and infra-spinatus, brachialis anticus, biceps, supinator longus, and probably the supinator brevis also. The resulting paralysis leaves an arm which cannot be abducted, and hangs by the side with the elbow extended and with marked pronation and internal rotation of both the upper arm and the forearm. As time passes, even with untreated cases, a partial recovery is seen. The flexion of the forearm at the elbow is practically always regained, and also abduction of the arm from the trunk, but in even moderate cases supination of the forearm always remains poor, and the external rotation of the humerus improves least of all, which accounts for the elevation of the elbow in attempting to bring the hand to the mouth, a fact that can be easily verified by anyone by attempting to put the thumb in the mouth while the humerus is strongly rotated inward. In the older cases with this trouble we find a lack of development of both muscles and bones of the affected extremity, and indeed of the whole shoulder girdle, which is evidently secondary to the paralysis and lack of use. One fact, however, is most striking in all cases that have persisted over some three years or more, and that is the notable lack of flaccidity, hypotonia and atrophy in the affected muscles. This is very striking if one compares one of these cases with weakness of the deltoid and spinati with a case where the same muscles have been left paralysed from an attack of poliomyelitis. In the latter the flaccid, atrophied condition of the deltoid allows one to see very clearly even at a distance the bony prominences about the shoulder, and the head of the humerus, while often there is a distinct space between the head of the humerus and the acromion due to the dropping of the whole arm, while in cases of obstetrical paralysis even though the muscles are much smaller than those of the unaffected shoulder there is almost never the extreme atrophy with prominence of the bony structures so striking in the cases of poliomyelitis.

The treatment of these cases may be divided into the operative and the non-operative. Of the first I shall speak very briefly. Two procedures in general have proved useful. The operations on joints to relieve limitation of motion from ligamentous contracture, and the transplantation of strong muscles to supplement the action of weak ones, the best results being from transplanting the pectoral, or the trapezius into the deltoid; and the excision of a portion of the brachial plexus at Erb's point, and the suture of the nerve trunks, as first practised, so far as I have been able to learn, by Kennedy of Glasgow, and later by Taylor of New York. Briefly this method should not be used too early, certainly not under a year, and probably not under two and a half or three years of age, and after seven or eight years of age it probably offers very little hope of improvement. It should be reserved for the severe cases which show little tendency to improvement, or which have not been treated. Probably in a good many of these severer cases it will be found impossible to trace and excise the injured portion of the plexus because of the surrounding scar tissue as in the case operated upon by Dr. Stone of which I have spoken. In cases where resection and suture of the plexus has been done it is important to remember that the operation must be followed by exercises and training of the muscles.

The second method of treatment of which I wish to speak which we have used at the Neurological Clinic at the Children's Hospital for a number of years, may be called that by massage and educational gymnastics. This method is based upon the belief that in most cases the affected muscles in time recover some slight power over which there is voluntary control, and that the awkward movements are due to the child using the stronger muscles, and accomplishing its object by using the arm in a different way from the natural movement. That this is so I think is proved by the very moderate atrophy of the affected muscles, and the very evident contraction that can be felt in them when the child attempts to use them. Thus abduction of the arm returns in part, some of the motion being due to movement of the scapula, but also from action of the deltoid, which serves at least to fix the humerus on the scapula. With some returning power in the affected muscles the arm is still used awkwardly, because the child learns to substitute the action of stronger muscles for those of weak ones, in order to execute the desired movement. For example when the forearm is flexed in order to bring the hand to the mouth, in case there is internal rotation of the humerus, the elbow must be abducted to compensate for this internal rotation. By a system of ingeniously devised plays the very small infant can be

taught to execute desired movements in a surprising way. To be successful this method of treatment should be started when the child is very young, preferably under one month, and must be persisted in for a number of years, with gradually lengthened vacations from treatment, till the child uses the arm naturally from habit. To these educational gymnastics we add passive movements, and also massage, to prevent the formation of deformities, and to aid in the growth of the limb.

We may divide the treatment into three parts:

1. Passive movements of the joints, shoulder, elbow, wrist and fingers, best done by someone who knows the anatomical possibilities and limitations of these joint movements. These movements need to be continued until the arm has entirely recovered.

2. Massage, of the gentle kneading form, to stimulate growth, which may be discontinued when the arm keeps up in growth with the unaffected one.

3. Exercises, to induce the child to use the arm, voluntarily, which vary with the age of the child.

(a) Under the age of two months one uses gentle irregular movements, carried out by the operator, and by the mother between treatments, such as moving the baby's hand and arm in various directions in imitation of voluntary movements made by the other arm.

(b) After two months when the baby begins to notice its hands and fingers more definite exercises are employed such as bending, stretching, or spreading the baby's fingers while the operator moves her own in a similar way. Very soon, especially if these movements are accompanied by some nursery rhyme the child will begin to imitate the movement and perform it without assistance. Besides the finger movements various others are used. The hand is flexed and extended at the wrist, and then carried to the neck thus flexing the forearm; the forearm is abducted and adducted with the hand supinated and the elbow bent and held at the side; arm extension in supination, where with the elbow bent and at the side the forearm is rotated outward, but within the limits of comfort, the hand in supination, the arm is extended by the operator in the direction of the line of the forearm. The next exercise consists in the operator lifting the arm to as near a vertical position as possible, from a position of extension in supination; then from the vertical position the elbow is lowered to the side bringing the hand to the shoulder or neck. From the position with the elbow bent and at the side the arm is stretched out and returned; and the arm in the horizontally stretched-out position is swung to describe a cone. These exercises are repeated a definite number of times, from two to eight each. Then come the exercises for the two arms together. The arms are stretched sideways three or four times and then the hands carried to the head; the arms are extended upward, and then returned to the bent position; the arms form a circle in front of the body the fingers touching and then the arms are carried upward until the hands are over the head and then separated and lowered to the sides. There are numerous variations of these exercises which are used while the child needs assistance in performing them, that is till ten or twelve months of age.

(c) At this age the child begins to rebel at interference and shows plainly a desire to act independently. From that time till about two years of age it is greatly absorbed in blocks, and it can be induced to reach in all of the directions given in the previous exercises in order to get the block which it wishes for building purposes provided it cannot get it otherwise. It can also be tempted to put blocks into a box held at various points calling for the muscular action desired. A box of blocks kept especially for the lesson is found to work well in keeping the interest of the child.

(d) At about eighteen months of age the child can be induced to return to the first exercises with the rhymes, but now done voluntarily, and dumb-bells, wands, balls, bean-bags and such things can be utilized, the same movements being carried out with these objects. At two and a half or three years the child will swing on a bar, walk into the corner with arms spread out, creep up the wall with the fingers and other exercises devised to use the desired movements. The last muscles to develop are usually the outward rotators of the humerus, and the supinators. These often need attention after the arm is apparently well. The special exercise for this stage is, with the elbow bent at the side, and the forearm in supination and abducted, with a small iron dumb-bell in the hand, the arm is extended in the direction of the line of the forearm.

We have obtained such excellent results at the Children's Hospital from such a system of what I have called educational gymnastics that we have entirely given up the use of electricity in cases of obstetrical paralysis, partly because it is much less effective, and partly because the muscles which need exercises and electrical stimulation the most, namely the spinati, practically cannot be stimulated by electricity because of the overlying fibres of the latissimus and trapezius.

As illustrations of some of our results with this treatment I wish to cite three cases:

CASE 1. Grace G. was first seen when three months of age. The labor had been hard and forceps were used. It was noticed very soon after birth that the left arm was not moved, but she always moved the fingers and hand, though the thumb was held in the palm most of the time. She was first seen in April, 1907. In July she could lift the arm

to the level of the mouth, but only flexed the elbow slightly, and there was still considerable pronation of the humerus and marked pronation of the forearm. In November she could flex more at the elbow, but supinated very little. By March, 1908, she could supinate about twenty degrees beyond the mid point, put the hand behind the head, and elevate fully. In September of that year she could elevate the arm to the perpendicular, put the hand behind the head, and the hand to the mouth without elevating the elbow, and supination, while the most affected movement, was two-thirds normal. In January, 1909, I have noted that supination seems to be to the full extent if the humerus is held in external rotation, and the whole trouble seems to consist in a partial loss of this external rotation. In December, 1912, when the arm was hanging by the side there was a little internal rotation of the humerus, but actively it could be rotated outward as well as the unaffected one, and all movements were normal, though at times the elbow was elevated. The left arm was half a centimeter shorter than the right, and the forearm six-tenths smaller while the circumference of the upper arms was the same.

CASE 2. Ellen P. was first seen on July 21, 1909, at the age of two weeks. The delivery had been by the breech, with no especial difficulty in the delivery of either the head or body. Immediately after birth it was noted that neither arm was moved, and that the right one was pronated but the left was not. When first seen the child had begun to move the left arm freely, but not the right one. This arm was held at the side and could not be abducted nor flexed, and was strongly pronated, while the movements of the wrist and fingers were freely made. By November the arm could be abducted to the level of the shoulder, flexion of the forearm was good, and there was some power of supination. In April, 1910, flexion of the forearm was normal, she could raise the hand to the level of the top of the head, supination was fair, and there was some external rotation possible of the humerus, though the pectoral was more tense than normal. In July, 1910, she could elevate the arm fully, and supinate the forearm completely, and the only distinct sign of the paralysis was a moderate internal rotation of the humerus, and that the child occasionally raised the elbow in putting the hand up. At the present time there is no difference in the length or circumference of the two arms, and all movements are normal.

CASE 3. Mary L. was seen first on October 11, 1905, at the age of eight weeks. There had been great difficulty in the delivery of the shoulders, and since birth the left arm had been motionless at the side except for some movements of the fingers. It could not be flexed at the elbow, was strongly rotated inward, and pronated, and there was no power of abduction. This case is mentioned because it was treated by the exercises alone, with no massage, and by April, 1909, she could make all movements well with the affected arm, and could supinate quite well, but there was considerable hanging behind in growth of the arm, though I have unfortunately been unable to find the measurements, but the difference was much more than in the cases which also received massage during the treatment, thus showing the importance of this in preventing the lagging behind in growth.

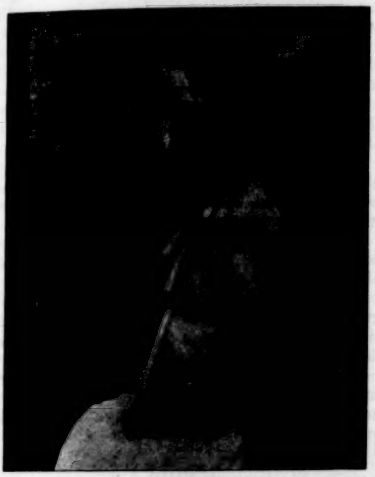
X.

ROUND SHOULDERS WITH SHORT CLAVICLES.

BY AUGUSTUS THORNDIKE, M.D.

The following is published because of peculiar features:—

Annie M., aged nine years, first came to the Children's Hospital in January, 1912. Her mother had noticed stooping shoulders since the age of four years, a condition which steadily grew worse. She had always been thin and puny. There was no lateral curvature, but the shoulders were very sloping and drooped far forward, producing a hollow chested appearance. The tips of the shoulders seemed very close to the nipples, and by measurement were less than two inches from them, while the scapulae projected like angel wings.



She began treatment at the hospital with two months of exercises. She had previously had them at home under direction of her physician without benefit. Entirely at the parents' request she entered the hospital wards to see if an operation could be done. The position of her shoulders and her general attitude is shown in the photographs. The muscles of the upper back were very little developed, while the great pectoral muscles were so stout and short that they effectually prevented throwing the shoulders back. The collar bone seemed short and the upper part of the body of the shoulderblade could be felt curving forward at a right angle to the plane of the lower portion.

Were the clavicles really short or did they seem so? I was unable to find any data relating to variations in the size of clavicles during the period of growth. We know that the size and shape are affected by rickets, osteomalacia, and that shortening occurs from fractures; in rare instances the bone or a large part of it may be absent at birth. No other assistance was obtained from the literature.

Certain definite proportions exist between the total height of the human body and that of parts, like the head, trunk, arms, legs. Painters and sculptors make use of these proportions. Why not extend this rule to other bones in the body? Why not apply it as a test to children's clavicles, and find out what relative proportion exists between the length of the clavicle and the height of the child? I accordingly measured these on three different occasions in the hospital wards. Twenty children were measured at one time, thirteen at another and six at another time, a total of thirty-nine children between the ages of two and twelve years. The ratio between the length of the clavicle and the height of the child averaged 9.97%. That is to say, the average of thirty-nine children showed the length of the clavicle to be 10% of the child's height. Individual measurements varied, the shortest was 8.8%, the longest 11.2%.

Annie M's. clavicles measured 4⅛ inches, her height 52 inches, the ratio 7.9%. In other

words, her collar bones were relatively 1⅝ shorter than the shortest, and in order to attain average proportions, each bone should be an inch longer.

Annie M. Round sloping shoulders, short collar bones.

This was explained to the parents, and at their request on March 18th, under ether, the clavicles were divided by an oblique osteotomy, and the great pectoral muscles cut near the insertion. Less than a half inch could be gained before cutting the pectorals. Much more than an inch afterwards. The blade of the osteotome was a quarter of an inch wide; it was made to enter the clavicle just outside the centre, and was directed toward the outer posterior corner of the bone. As the outer half of the clavicle is very thin, vertically, but in an anteroposterior direction widens greatly at the outward end, the cut surfaces of the bone were still in contact over a large area even when the outer fragment had uncovered an inch of the inner fragment. There was little tendency to displacement. Catgut sutures were used, one over the clavicle, two over the pectoral incisions on each side; small sterilized gauze dressings were applied with adhesive plaster strips, and a short light plaster of Paris jacket applied, carefully modelled over the shoulders, the upper chest and the back. She was allowed free use of the arms below the elbow; in two days she could sit up and feed herself; and in three days she was partially dressed, walking about the ward. The discomfort was very little, the wounds healed by first intention; when the plaster was removed in three weeks the right clavicle measured 5⅛ inches, the left 5¼ inches, a gain of ⅞ and of one inch respectively.

Three months after operation the gain was slight, but she was broader across the shoulders, and her parents were pleased. The back muscles were still very thin and weak; she was exercising them and slowly developing them.

Since then another year has passed. Her attitude is really much improved; she can assume a fairly normal position and the chest expansion is much greater, but it may still be necessary to straighten the scapulae by an operation. The writer hoped that if she could hold her shoulders in a fairly normal position for a year, the body of the scapula would straighten itself.

This is the only instance I have recognized of short clavicles. Was the condition due to an early arrest of growth in the bone during fetal life, or did it result from the unusual forces acting upon the clavicle from the over-powerful pectoral muscles opposed by very weak trapezii and rhomboid muscles and serratus.

Oblique osteotomy for lengthening a clavicle had been already performed by Dr. F. E. Peckham of Providence for a patient with considerable shortening from a healed fracture and scoliosis. This I did not know at the time I operated.

XI.

Removal of Foreign Bodies From the Oesophagus and Lower Air Passages in Children.

By D. Crosby Greene, M.D.,

and

F. E. Garland, M.D.

During the past five years of our service at the Children's Hospital, we have removed foreign bodies obstructing the oesophagus or lower air passages in twenty cases, by means of endoscopy. Ten of these foreign bodies were located in the oesophagus, three in the larynx, three in the trachea, and four in the bronchi.[1] Prompt recovery followed in all but two of the cases. In one of these, a piece of fig in the left primary bronchus was not completely removed, and later caused a pulmonary abscess which resulted fatally several weeks after bronchoscopy. The other case was brought into the hospital in a state of prostration, having been mistakenly treated for a week for diphtheria, by successive intubations and several doses of antitoxin. The child was almost moribund at the time, and removal of a peanut from the left bronchus was followed by death in a few hours.

For obvious reasons the majority of foreign bodies lodged in the oesophagus or lower air passages are found in young children.

The problem of their removal in children as contrasted with that in adults presents two main differences: the first has to do with the anesthesia,[2] and the second with the smaller calibre of the passages. Whereas in adults with a moderate degree of self control local

anesthesia may be successfully employed, we are convinced that in children peroral endoscopy can be performed more successfully, with less trauma, and with less shock to the patient under a carefully conducted general anesthesia combined with local anesthesia. An exception is made in those cases in which the foreign body is of sufficient size to produce marked obstruction of the larynx or trachea. In such cases we have done tracheotomy under local anesthesia. In most cases we have used ether preceded one hour by a subcutaneous injection of atropine in the dose appropriate to the age of the child and enough to produce a distinct physiological effect. Ether is administered slowly by the open method, and when the child is deeply narcotized, the larynx and trachea are swabbed with a solution of cocain (10%) and adrenalin (1 to 1000.)[3]

If these preliminaries are carried out, the patient is brought up to the stage of operation with the larynx, trachea, and bronchi comparatively free of mucous, and conditions are most favorable for rapid discovery and extraction of the foreign body. The importance of these preliminaries can only be realized by one who has tried to work in the trachea and bronchi of a patient in whom they have been omitted. The presence of copious mucus and the irritability of the mucous membrane, made worse by the constant swabbing which is necessary in order to clear the field, combine to enhance many times the difficulties of the procedure.

The smaller calibre of the air passages in children naturally necessitates the use of smaller tubes in bronchoscopy and oesophagoscopy. We have found in practice that a tube 7 m. m. in diameter is small enough to permit exploration of the main bronchi in the smallest children. The bronchoscopes used are all of Jackson's pattern. For laryngeal work we have used both Jackson's and Mosher's small specula. The latter has proved to have a distinct advantage over the former in operative work by reason of its open construction which permits a better view of the field when instruments are being introduced and used. In oesophageal work we give the preference to Mosher's oval oesophagoscopes, because the oval shape in a lumen of a given circumference again gives better opportunity for operative work. Altogether the best forceps which we have used is Coolidge's. It combines admirably two essential mechanical features: (1) it is operated by a handle and trigger entirely outside the line of vision; (2) closure of the forceps is accomplished without any movement of the blades in the line of direction toward or away from the object to be grasped. The same handle may be used for long or short distance work, by fitting to it the tips of appropriate length.

The anesthetized patient is put in the dorsal recumbent position with the head hanging over the end of the operating table and supported by an assistant. The laryngeal speculum is then introduced and inspection made of the hypopharynx and larynx. If the oesophagus is to be explored, the laryngeal speculum is now withdrawn and an oesophagoscope with mandrin guide is then manipulated into the oesophagus. As soon as the upper constriction of the oesophagus is passed, the mandrin is withdrawn and the oesophagoscope slowly passed downwards, the lumen being always kept in view for inspection.

If the trachea or bronchi are to be explored, the laryngeal speculum is not withdrawn until, after cocainization of the larynx and trachea, a bronchoscope has been passed through the glottis into the trachea. The speculum is then withdrawn and the bronchoscope passed downward through the trachea into the bronchi.

Peroral endoscopy is not indicated for recovery of a foreign body of considerable size obstructing the trachea, such as a peanut or a bean. Such objects are likely to slip out of the grasp of the forceps in the attempt at extraction, and an emergency tracheotomy under difficult conditions may be required. It seems to us much better to open the trachea at the start, under local anesthesia if the dyspnea is severe, and carry on endoscopy through the tracheal opening.

REFERENCES.

[1] The objects recovered from the esophagus were: 1 collar button, 1 medal, 1 Canadian two-cent piece, 2 one-cent pieces, 1 orange pulp, 1 piece of bent wire, 2 twenty-five cent. pieces, 1 cherry stone, 1 piece of beef; from the larynx: 1 piece of egg shell, 1 piece of peanut shell, 1 piece of tin; from the trachea: 1 peanut, 1 piece of glass, 1 broken tracheal cannula; from the bronchi: 1 piece of fig, and fragments of peanuts in three cases.

[2] Jackson has recently advocated doing peroral endoscopy in children without any anesthesia. We believe that our record indicates the safety of general anesthesia under proper precautions—while its advantages are obvious.

[3] When the esophagus only is to be examined, local anesthetization is omitted.

XII.

THE INFLUENCE OF ALKALIES UPON GASTRIC MOTILITY.

BY MAYNARD LADD, M.D.

THE purpose of the work which forms the basis of this preliminary study has been to determine the effects of alkalies upon gastric motility in infants so far as they can be demonstrated by serial radiographs taken after the administration of milk-mixtures containing bismuth.

The use of alkalies, such as lime water and bicarbonate of soda, has been a common practice in infant feeding. Recently considerable doubt has been expressed, both as to the desirability of their use and as to whether their action is that which is theoretically claimed for them. When lime water or sodium bicarbonate is added to cow's milk, a basic calcium or sodi-

um-casein is formed which is not acted upon by rennet and will not form a curd even in the presence of soluble calcium salts. It would seem, therefore, that a considerable degree of alkalinity in a milk mixture would suspend gastric digestion by its inhibitory action upon rennet coagulation and, therefore, by allowing rapid emptying of the stomach throw the burden of digestion upon the duodenum. Whether this action really occurs ought to be demonstrable by means of serial radiographs of the infant's stomach. The other reasons for or against the use of alkalies in infant feeding do not enter into the scope of this investigation.

There are certain facts in regard to gastric motility observed in infants by this method which may be briefly stated in review, as bearing upon this subject. In two previous papers I have drawn inferences which my subsequent work has strengthened.* The cases studied to date represent 15 different infants, 36 series of experiments and about 275 radiographs. This is a comparatively small number, but allows us to make certain observations which are probably correct.

First of all, irrespective of the age of the child, or of the composition of the food, the gastric contents begin to pass into the duodenum at once and with considerable rapidity, until at the end of two hours, in the majority of cases, by far the greater part of the feeding has been expelled. The rate of discharge into the duodenum then becomes much slower and under certain conditions the emptying time may be greatly prolonged before it is complete. A new feeding tends to stimulate peristalsis and to push out ahead of it the residue of the previous feeding. If no new feeding is introduced, the emptying time depends partly upon the character of the food and partly upon the individual equation of the infant, or upon conditions of digestion which can not be determined by serial radiography.

As examples of this personal equation in gastric motility, I may mention three infants of approximately the same age and taking the same formula and the same amount at a feeding, who required one 2½, one 3¾ and one 4½ hours to empty the stomach.

The same three infants on another fomula required one 7½, one 4½ and one 6 hours for complete emptying of the stomach.

Moreover, in the same infants, we see marked differences in the rate at which the food leaves the stomach, which depend upon variations in the composition of the mixture. One infant of 7 months, for instance, required on different occasions, 2½, 4½, 7½ and 6 hours for complete emptying of the stomach, according to the character of the food given. The details of the experiments upon which these statements are made may be found in the articles to which I have referred.

* "Gastric Motility in Infants as Shown by the Roentgen Ray." *Am. Jour. Dis. Children*, May, 1913, vol. 5, pp. 345-358; and "Influence of Variations of Diet Upon Gastric Motility in Infants," *Arch. Ped.*, October, 1913.

I have not been able to show that the emptying time is always uniform in the same baby for a given formula. In fact, it is very evident that certain states of digestion occur which influence decidedly the gastric motility even when there has been no change in the food. This fact makes it difficult to draw definite conclusions as to the influence of variations in the composition of the food upon molitiy. It would appear that under certain conditions, not easily explained, stasis results and food remains in the stomach for many hours, unless its expulsion is encouraged by giving a new feeding.

So far as I have been able to determine, neither the percentage of sugar (up to the limit of 7 per cent.), nor its variety (lactose or maltose), has any influence upon gastric motility.

If the proteins are kept low, even the fats fail to show any constant tendency to prolong the emptying time, which, in several of my experiments, was the same whether the mixture was fat free or contained an amount of fat as high as four per cent. If the percentage of fat influences the motility at all, the effect is not striking.

In regard to the casein, however, we do see a marked effect upon motility, depending upon whether the percentage of casein is very low or very high and more particularly according to the form in which it is given. I have found generally that the full protein of milk (3.50%) considerably prolongs the emptying time, but that this effect is much more marked in some instances than in others. For example, in one child, the difference in the emptying time between a whey protein mixture of .90/.60 and one of 3.50 total protein (the fat and sugar being the same), was 2½ hours and 6½ hours. On the other hand, another child accustomed to high proteins from birth, took 4½ hours to empty its stomach on this same mixture containing 3.50 per cent. casein.

When the casein is converted into a non-coagulable form either by precipitation, or by the action of lactic acid cultures, forming the lactate of casein, the emptying time is much accelerated —varying from 2½ to 3 and 3½ hours. This is the most constant effect of variation in the composition of the food elements which I have been able to observe.

Whether the amount of energy involved in the digestion of food is influenced by the time it stays in the stomach is a point which seems to me of some importance in metabolism experiments upon infants. For example, in one experiment, an infant on a 0.00 fat, 6.6 sugar, and 3.50 protein required 6 hours to empty its stomach; the same infant on the same percentage formula but with the casein precipitated, discharged its contents into the duodenum in 2½ hours. The caloric value of the food was the same in each case, but the difference in the form in which the casein was given made a difference of 3½ hours in the emptying time. It would seem as if a greater amount of work was done in one case

than in another. Whether or not this is a point of importance in metabolism experiments, it is certainly one which must always be considered when we are taking serial radiographs for the purpose of determining gastric stasis in infants.

The following experiments to determine the influence of considerable quantities of alkalies on gastric motility, must always be judged in reference to the foregoing facts. There have been three infants studied. The results in each series may be briefly summarized as follows:

FIRST SERIES.

1. McGINNIS, Nov 18. A breast fed infant of three and a half months. Two level teaspoonfuls of bismuth subcarbonate were given in one ounce of water and the baby was allowed to nurse until the amount of the feeding was four ounces in weight. Feeding began at 9.30 a.m. Radiographs at 10 a. m., 12, 1, 1.30. Breast feeding without bismuth at 1 p. m. Plates show considerable residue at the end of 3½ hours. The last plate shows very clearly how the new feeding pushes the residue of the old feeding into the pyloric end of the stomach without mixing intimately with it.

2. McGINNIS, Dec. 1. The same procedure was carried out in the second series, except that one ounce of lime water was given in place of the plain water, making the lime water 25% of the total mixture of breast milk. Feeding begun at 9.30 a. m. Radiographs at 10 a. m., 12, 1.15. The last plate shows the stomach practically emptied in 3¾ hours in contrast to the large residue after 3½ hours in the previous experiment in which no lime water was given. Considerable difference is shown in the amount of stomach contents in the two plates at the end of the two hours; after the feeding with lime water the residue is considerably less, but the most striking feature is the rapid discharge in the last 1¾ hours.

SECOND SERIES.

1. POMMETT, Nov. 17. Three and one-half months. The food in this series was: Fat .0.00, Lactose 6.50, Protein 1.75. No alkalinity. Amount 3½ ounces. Tube feeding at 9 a. m. Radiographs at 9, 11, 12, 2. Stomach practically empty in five hours. This series represents very typically the normal discharge of the gastric contents on such a mixture. Notice the very slight change in the condition during the third hour of digestion.

2. Nov. 9. Same formula. Lime water, 25% of the total mixture. Tube feeding at 12.15 M. Radiographs at 12.15, 2.15, 3.15 and 4.10. Stomach practically empty in four hours (one hour less than in the series without lime water.) Notice the rapid discharge of the contents during the third hour of digestion.

3. Nov. 24. Same formula. Lime water 50% of the total mixture. Tube feeding at 11 a. m. Radiographs at 11, 1, 2.15. Stomach practically empty in 3¼ hours. The discharge of the contents in the third hour is still more rapid than in the series of Nov. 19.

The presence of lime water in this series apparently hastened the discharge of food into the duodenum, by 1 hour and 1¾ hours, respectively.

4. Nov. 26. Same formula, protein in form of precipitated casein. No alkalinity. Tube feeding at 11. Radiographs at 11, 1, 2.30. Stomach practically empty in 3½ hours. That is, when the casein was previously precipitated, the discharge of the contents was practically as rapid as in the series of Nov. 24, when 50% of the total mixture was lime water.

5. Nov. 29. Same formula. Protein in form of precipitated casein. Lime water 25% of total mixture. Tube feeding at 11.30 a. m. Radiographs at 11.30, 1.30. Stomach empty in two hours.

This experiment loses some of its significance in view of the fact that much of the casein became clogged in the tube so that the stomach contents were largely a sugar solution and bismuth. It is interesting, however, to note the rapid disposal of the bismuth, in the absence of any considerable amount of casein.

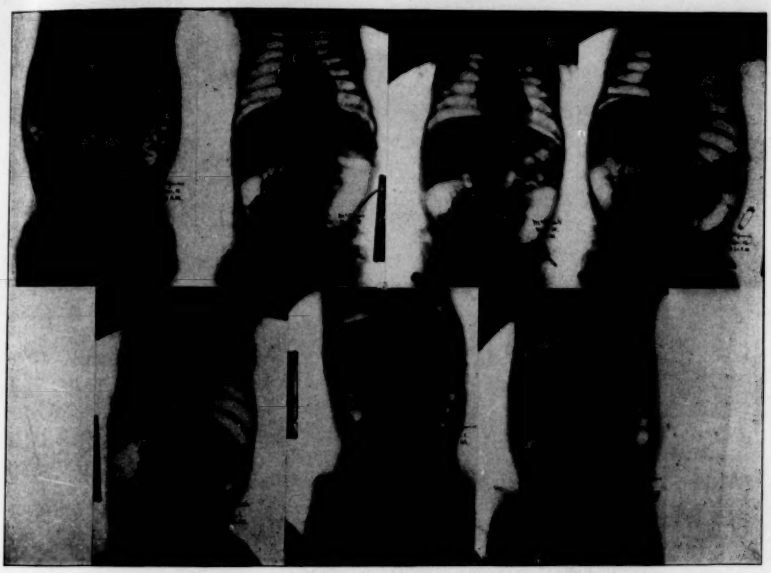
6. Dec. 2 Repetition of experiment of Nov. 29. Tube feeding at 9.30 a. m. Radiographs at 9.30, 11.30, 12.30, 1.15. Stomach practically empty in 3¾ hours.

Experiments 4 and 6, apparently indicate that when the casein is already precipated before administration, the lime water has no marked effect upon gastric motility, the discharge of the food into the duodenum being hastened by the subdivided condition of the casein, the lime water itself exerting no influence.

7. Dec. 4. Same formula. Protein in form of precipitated casein. Lime water 50% of the total mixture. Tube feeding at 10.30. Radiographs at 10.45, 12.30, 1.30, 2.30, 3.30. Stomach practically empty in five hours.

In this series, with lime 50% of the total mixture, considerable stasis is seen to exist during the third hour of digestion and the emptying time as a whole is prolonged. A similar, and even more pronounced state of stasis is seen in the third series, Dec. 15 (below).

THIRD SERIES.



CUNNINGHAM. 8½ months. The food in this series was: Fat 2.00, Lactose 7.00, Protein 2.25. Amount seven ounces.

1. Dec. 13. No lime water. Tube feeding at 9 a. m. Radiographs at 9. 11.45, 1.15, 2. Stomach practically empty in five hours. Compare with Pommett, Nov. 17. The normal emptying time was the same for an infant of 8½ months, taking seven ounces, as for one of 3½ months taking 3½ ounces.

11.30 A. M.

12 M.

9.30 A. M.

11.30 A. M.

12.30 P.M.

2 P. M.

Cunningham. Jan. 2.

2A. Dec. 15. Same formula. Lime water 25% of total mixture. Tube feeding at 9 a. m. Radiographs at 9.30, 11.30, 1, 2, 3, and 4 p. m. Stomach still contains food at seven hours.

This case illustrates the occasional condition of stasis one sees when the food is high in casein.

2B. Dec. 29. Repetition of 2A. Tube feeding at 9.30 a. m. Radiographs at 9.30, 11.15, 12.30, 1.30. Stomach practically empty in three hours.

The experiment 2 B. is similar in result to that in the McGinnis and Pommett series, the emptying time being diminished by 2 hours, when the feeding was strongly alkaline. The anomalous condition of stasis in 2 A. is difficult to explain with any degree of certainty.

3A. Dec. 19. Same formula. Sodium citrate, 14 grains. Tube feeding at 7.30. Radiographs at 9.30 lying down, 9.35 sitting up, 11.30 and 1 p. m. Stomach practically empty in 5½ hours. The difference in position when the body is erect, causes the pyloric end of the stomach to be slightly lowered, the cardiac portion remaining unaffected.

3B. Dec. 31. Repetition of 3A. Tube feeding at 9.45 a. m. Radiographs at 9.45, 11.45, 12.45 and 2.10. Stomach practically empty in 4½ hours.

The influence of sodium citrate in this series would, therefore, seem to be very little as far as gastric motility is concerned. It is certainly less marked than in the series in which lime water and sodium bicarbonate (see below) were use.

4A. Dec. 22. Same formula. Sodium bicarbonate 14 grains. Tube feeding 9.30. Radiographs at 9.30 lying down, 9.35 sitting up, 11.30, 12. Stomach practically empty in 2½ hours.

4B. Jan. 2. Repetition of 4A. Tube feeding at 9.30 a. m. Radiographs at 9.30, 11.30, 12.30, and 2. Stomach practically empty in four hours.

The action of sodium bicarbonate is, on the whole, even more striking than that of lime water, but the difference may not be borne out in a larger series of cases.

In this preliminary work, I have made no effort to attempt to judge of the effects of anything but large amounts of alkalies. Lime water and bicarbonate of soda unquestionably tend to hasten the discharge of the gastric contents into the duodenum. This effect is sometimes seen in the more rapid discharge of the contents in the first two hours of digestion, but that difference is not as striking as one would expect from the theories in regard to the use of alkalies which have previously been held. The most important point brought out by these experiments is the shortening of the latter half or the digestive period by the use of alkalies. The effect on gastric motility is, therefore, probably due almost wholly to the action of alkalies, upon the casein curd.

XIII.

A Study of the Etiology in One Hundred and Seventy-Five Epileptic Children.

By Arthur Willard Fairbanks, M.D.

Notwithstanding the fact that epilepsy is one of the oldest of diseases its causation still remains a matter of uncertainty and contention, although a vast mass of literature exists concerning this particular phase of the subject.

I believe that this is due in great part to two facts. In the first place the conditions embraced in the term "Epilepsy" was for many generations regarded as a disease, *sui generi* and even at the present time this view seems to still persist, if one may judge by the argument employed by many writers, especially those who advocate the hereditary theory of the affection. In the second place, and this seems to me the more important of the two facts, the great majority of published statistics deal with cases studied in adults, or present data obtained from clinical material of all ages.

It is the main purpose of this paper to show that the truth concerning the cause of the majority of epileptic cases cannot be determined by the exclusive study of adult material, while the inclusion of the incomplete data obtained from such cases, with the more accurate data obtainable from the parents in the case of the child, cannot fail to lessen the value of the latter, and lead to erroneous conclusions as to the real incidence of acquired epilepsy as compared with the inherited affection. To return however for the moment to the first proposition. It would seem trite to say that epilepsy is a condition not a disease, were it not for the evidence that the old conception continues to prevail. Epilepsy cannot be regarded as a disease in the sense in which the term should be strictly employed. The longer one studies the cases that come under his observation the more he will find it impossible to give a concise and unqualified definition of any clinical entity, or in other words a disease that as such may be termed "Epilepsy," and the stronger will become his conviction that the state so designated is merely an instability of the central nervous organization; an inability of the nerve centres to maintain their equilibrium in the presence of either ordinary or extraordinary stimulation from without. The frequency, the persistency, and the degree of this instability of the central nervous system furnish us with a convenient basis of classification, which is however merely a convenience, and in no respect a justification for arbitrary nosological differentiation.

The real question of moment in any single case is not "Is this epilepsy or is it not?" but "Why does this individual's central nervous

system respond in this manner to these stimuli, wherever they may arise or whatever their nature may happen to be, when the central nervous system of other individuals does not so react?"

From this point of view all of the innumerable exciting factors of the individual attacks, so often emphasized as of importance in the etiology of epilepsy, become immaterial in so-far as the solution of the real cause of the unstable state of the individual is concerned. They are merely the immediately exciting factors that for the moment overthrow the poorly balanced nervous system. Over-emphasis of these exciting factors of individual epileptic or eclamptic attack serves rather to cloud than to clarify our understanding of the fundamental cause of the condition. Innumerable articles have appeared, and are constantly appearing, in medical literature, the sole purport of which is the attempt to prove this or that exciting factor the real or fundamental causation of epilepsy. This tendency, persisting even at the present time, is to be deplored, for it only delays the recognition of the fact that every conceivable external stimulus may be sufficient to overthrow the static balance of the central nervous mechanism when its static balance is below the normal average of stability, and only then. What are the conditions that are responsible for this defective equilibrium? We must first consider the conditions that make the normal development of stability impossible. In the first place the parent cells may not be endowed with those inherent qualities that permit the ultimate attainment of relative stability in the developed organism. In such instances the instability is inherited. It is of course impossible to assert the existence of this inherited instability unless there exists in the history of the ascendents of the individual positive evidence of similar instability.

Second, given parent cells with normal inherent stable qualities, some influence such as trauma or disease in the mother, (or in the placenta, after the third month) may be brought to bear on the embryo in utero to impair the development of the central nervous system, and consequently to prevent the evolution of stability. Such injuries to the embryonic development, if they occur during the first three months of pregnancy, may be evident otherwise in the form of anatomical defects or malformations, and, even later, abnormalities in the pregnancy, especially those associated with insufficient room in utero for the proper developments of the foetus, (as in the case of twins) may produce marked anatomical defects, particularly microcephalus. In the absence of such gross defects, only the history of some disturbance of the normal course of pregnancy will suggest the possible injury of the embryo. Any condition however that has retarded the cerebral development of the foetus at any time during the first eight months, is extremely likely to produce some degree of microcephalus, evident at birth. When present it is extremely suggestive of some disturbance of the normal conditions of pregnancy. It may be relative to the otherwise normal physical development of the child or it may be but a part of a general defective physical development. Its importance as far as antenatal origin is concerned lies in its being present at birth. Premature termination of the pregnancy, by sending the child into the world in an immature and therefore unstable state, is also occasionally an undoubted factor.

Third, with the embryo normally developed, there still remains, as a possible factor in impairment of stability, the incidence of trauma and disease. The period of birth is the time in the life of every child when the brain is exposed to the greatest danger. It is at this period, therefore that we would expect to find the origin of structural damage of the brain, and in fact do find frequent evidence of such structural damage, with a history of some abnormality of birth as a probable cause of the injury.

Let us consider some of the incidents of birth that may cause injury to the cerebral structure. An unusually large head passing through a pelvic strait of normal diameter may require so much compression of the cranial bones that injury to the cranial contents is unavoidable, or a normal head of average diameter passing through a pelvic canal of minor diameters may entail similar damage. Then also a normal head may be forced through a normal pelvis with such rapidity by unusually forceful contractions of the uterus that there is no time for gradual accommodation of the cranial bones to the passage through which they must pass and rapid cranial compression occurs without consideration for the safety of the underlying brain and serious damage results. This I am confident is not rarely a cause of injury. It is however usually overlooked because the labor is described by the mother as "an easy one" and this is accepted as evidence that it has also been an easy one for the child, which is by no means necessarily the fact. I have had reason for years to regard those labors in which the child is born after a few short strong pains, often before the accoucheur's arrival, as by no means favorable for the child. The greatest care must be observed in taking the birth history of a child not to too readily accept the mother's assurance that the labor "was normal." She is referring to her own experience rather than to that of the child. Not infrequently, when we have received assurance that the birth was normal, it will be found by careful enquiry that, as a matter of fact, the child was more or less asphyxiated, and that some effort was necessary to induce respiration. Such a fact must be given full value as a possible source of cerebral injury. Also in labors in which the baby is born before the physician's arrival the

possibility of a twisted cord with its secondary effect on the cerebral circulation always should be borne in mind. In other instances owing to inertia or to minor pelvis in the mother, or to a large head, etc., it may become necessary to apply forceps, which may produce cerebral damage directly, or indirectly by rapid extraction of the head before it has an opportunity to adapt itself to the passage through the pelvis.

In breech presentations with rapid delivery of the after-coming head there may be resultant injury either directly by compression or through venous engorgement consequent on the delayed delivery of the head. Long delay of an otherwise normal labor by premature rupture of the membranes may also be attended by cerebral trauma. Often when we do not obtain any positive history of abnormal labor from the mother we may see positive evidence of it in the child in the shape of gross cranial deformity, or by the presence of cranial scars, or spastic paralysis, convulsions during the first few days or weeks subsequent to birth, or by marked delay in the early development of the infant. The numerous contingencies, above referred to, indicate how great is the danger to which the child's brain is exposed during birth.

After birth there exists throughout the years of childhood the incidence of trauma and disease as cause of cerebral injury. The permanent structural damage produced by diseases that directly affect the brain, as meningitis, encephalitis and hydrocephalus, is a matter of common clinical observation, while it is by no means a rare clinical experience to observe the serious injury done to the central nervous structure by the infectious diseases, either directly by the action of their toxin or indirectly through vascular lesions. All of these many sources of acquired cerebral damage must be considered when we are searching for the etiology of chronic cerebral disturbance or defect.

We find that they are the most common factor in the production of spastic paralysis and of mental deficiency in childhood, and we shall find that they are the largest single positive feature of the histories we obtain in the study of epileptic children.

I have selected 175 cases of epileptic children in which accurate data in reference to the family and personal history were obtained, and careful examinations were made for objective evidence of cerebral injury or physical defects. These cases were chosen solely on account of the completeness of the historic and clinical data. Otherwise they were taken consecutively in the order of their first visit to the hospital. They comprise children up to the fourteenth year inclusive.

In a critical study of these cases with reference to the etiology we find that the most careful enquiry revealed, in only 12 instances, any trace of convulsive attacks or of petit mal in the ancestors or in other members of the family.

In all of these cases however the hereditary taint was pronounced and in striking contrast to all of the rest of the series. Two fathers were epileptic; one mother had petit mal in childhood and another convulsions in childhood and two of her children, brothers of my patient, died in convulsions in early childhood. In another instance the parents were unaffected but another of their children died in convulsions and two cousins were epileptic. In the case of a child of 3, a maternal cousin, a boy of 10 was epileptic and a paternal aunt insane. The rest of these cases presented an equally marked familial taint. It is an interesting fact that only two of these children presented other evidence than the epilepsy of cerebral defect, namely, mental deficiency, and one of them born prematurely and the other by the use of instruments. They were the only instances of this series in which there was anything abnormal about the birth. The familial taint was definite however in both cases. In none of this series was spastic paralysis present.

One case I am unable to classify, but it should perhaps be mentioned here and may belong to the hereditary series. This was a child of 8 years, whose paternal uncle was epileptic. The boy presented marked degenerative stigmata, in the form of web fingers, supernumerary toes, cryptorchism and hypospadias. In addition he was hydrocephalic and had Hutchinsonian teeth. He was born after severe prolonged labor with the cord twisted about his neck, and he was idiotic and diplegic. The convulsions appeared immediately after birth lasting all night, and recurred for twenty-one months with great frequency, and thereafter infrequently to the eighth year. There can be no doubt that this child was injured at birth but there is equally little doubt that there was a syphilitic as well as a familial degenerative taint.

I do not find among my cases any that can be ascribed to disease during pregnancy, with the exception possibly of some of the syphilitic cases which will be considered in a class by themselves later.

Two cases were exposed to trauma during pregnancy by the attempt to induce miscarriage which had been successful several times previously. Both cases were born at term. Both of these children showed other indications of cerebral injury. One was feeble-minded, and had strabismus, the other increase of the deep reflexes and unsteady gait. In two cases trauma was undoubtedly the cause of premature birth. These will be considered under that classification.

In four instances the children were the product of twin pregnancies. All were born at term. Two presented other signs of organic brain defect. One was a light case of mental deficiency and showed a hemiparesis, the other

was mentally defective. In both of these cases, and in one of the others the other twin died in early infancy.

In only one case was it possible to ascertain whether the patient was the first or second delivered. That one was the first born, the other child dying at 7 months of "weakness."

In six instances the children were born prematurely, 2 at 7 months, the others at 8 months. In two of these instances the mothers suffered falls in the fifth month of pregnancy (one 7 months child) and in the seventh month of pregnancy (an 8 months child) respectively. Both of these children were feeble minded, and one was also blind. The others presented no cerebral defects except the convulsive attacks. One child however presented anatomical degenerative stigmata, in the teeth, face, palate, and ears. Beyond the statement that the mother and her family were "nervous" there was an entirely negative family history in this case.

In 43 cases there were conditions during the birth of the children that exposed the brain to extraordinary danger. Of these, 14 were born after severe or prolonged labor, by the aid of forceps, but not asphyxiated. Of these, 8 were feeble minded, 3 were hemiplegic, 1 was diplegic, and 2 showed marks of cranial trauma at birth. Both of the latter were feeble minded, as were also the diplegic and one hemiplegic, and are included among the 8 mentioned as mentally defective. Ten were born by the use of forceps and were asphyxiated. Of these, 4 were feeble minded, 3 were hemiplegic, one paraplegic, and 3 showed definite marks of cranial trauma at birth. Two of the hemiplegics and the paraplegic were mentally defective, as were also 2 of those presenting evidence at birth of cranial trauma. One case was not only feeble minded and hemiplegic but also showed marks of cranial injury. One of the series was one of twins, the other child being still-born, and this may also have been a factor.

Six were born after severe labor but without the use of forceps and as far as known not asphyxiated. Of these 4 were feeble minded. None of them were paralytic.

Four were born after severe labor, without forceps, and were asphyxiated. Of these, 2 were feeble minded and one of these was also paraplegic.

Two were large children born, after severe labor, with forceps. These presented no cerebral defect other than the epilepsy.

Two were born after prolonged dry labor, and one was asphyxiated. The other child was feeble minded. Two were born quickly before the doctor's arrival. One was feeble minded and the other was hemiplegic. Of the remaining cases of this series 1 was a brow presentation with forceps delivery; another a footling, born after severe labor and asphyxiated, and the other was a placenta praevia case. These cases were the only cases in the series that did not show some evidence of cerebral abnormality, other than the epilepsy itself. Thus of these epileptic children, whose birth was in some one or more respects abnormal, 70% presented other evidence of cerebral defect than the epilepsy, and 23% presented objective evidence of structural damage of the brain in the form of spastic paralysis, and 14% presented evidence of cranial injury, two of these being spastic.

The high percentage of cerebral defects in these children, even exclusive of the epilepsy, indicates how frequent is the incidence of cerebral trauma during birth. When we consider how many births, considered normal by the mother and by the physician, may not really be so for the child, but may be attended by slight injury not producing gross evidence of its presence, we may understand how this slight structural injury may later make its existence evident in the form of epilepsy or mental defect.

Eight cases were probably syphilitic in origin. In all but two the effect of the disease was very evident in the many miscarriages and early infant mortality shown by the history. In one of the two exceptions the father acquired syphilis 7 years before the child's birth and one of his children died in convulsions 2 to 3 months old. The father of the other child died of "softening of the brain" while the case was under observation. Five of the 8 cases were mentally defective. One child of 3 years who had had innumerable attacks of all degrees of severity from its earliest infancy promptly responded to iodide of potassium, improved markedly in intelligence and no recurrence of the epilepsy occurred although the child was under observation for a year afterwards. These cases do not respond to bromide to any material degree.

Fifteen of the series had suffered cranial injury after birth and antecedent to the appearance of the epilepsy. Many of these injuries were accompanied by immediately serious symptoms; unconsciousness from half an hour to thirty-six hours, vomiting, hemiparesis, facial paresis, and in one case blindness and deafness for four weeks, while others did not seem at the time seriously hurt, but soon showed mental deterioration. One case will suffice to illustrate this. This child developed normally to the beginning of the second year when she had a fall, and three months later another, striking her right side. Mental progress ceased and when examined she showed a left hemiparesis. The epilepsy appeared shortly after the fall and was at first concentrated on the left. These cases are of very instructive character, but it is not possible within the limits of this paper to cite their details. Two of the children however might have been classed otherwise for one was premature and the other a forceps delivery, but as neither had any convulsion until after the blow on the head, and the initial attack occurred in unquestionable relationship to the trauma, they

seem properly to belong here. A greater susceptibility to cerebral trauma may have existed however in these two cases.

Twenty-two of the children were perfectly well until the onset of meningitis or encephalitis, during the convalescence, or following the recovery from which epilepsy appeared. Six of these children were feeble minded and 6 were hemiplegic.

Five cases could be traced to an attack of pertussis, in two instances at the age of a few weeks, in one at sixteen months, and in two at two years. One was hemiplegic and one had strabismus. If these cases owe their origin to pertussis as seems probable, the damage to the brain was undoubtedly circulatory not toxic. In a somewhat different class are the next four cases which originated from infections, two during dysentery, the others following diphtheria and measles. It is somewhat difficult to determine the manner in which the cerebral trauma was caused. In one of the dysentery cases the severity of the symptoms indicate meningo-encephalitis, the 2½ year old child having lain for eight days unconscious, with retracted head. None of these children were spastic, one had deteriorated mentally since the measles, was under observation seven years, and finally committed to an institution.

In 53 cases no definite etiology could be determined. 23 presented evidence of cerebral defect other than the epilepsy, 14 feeble minded, (several showed cranial deformity) 7 hemiplegic, 1 paraplegic and 1 hydrocephalic. Thus a considerable number of these otherwise unexplained cases presented objective evidence of cerebral defect or deficiency, the result of trauma or disease.

The study of these 175 cases confirms an opinion I have held for many years, as the result of the observation of many hundred epileptic children, that heredity is a minor factor in the etiology of epilepsy, whenever the disease is studied at such an age that the true details of the past and family history of the victim can be obtained. These data are obtainable in the case of children to an infinitely greater extent than when the disease is investigated only in adults. Both the data and physical examination of epileptic children indicate that the affection in the majority of instances is the result of acquired cerebral injury from trauma or disease.

XIV.

Hemorrhage Following Tonsillectomy.

By F. E. Garland, M.D.,

and

D. Crosby Greene, M.D.

There is a wide variance of opinion among medical men in regard to the frequency of hemorrhage after tonsillectomy. Some men of large experience report but one or two cases of hemorrhage in a thousand cases operated upon. Others, who have done an equal amount of work put the number much higher,—one hemorrhage to very hundred, or even fifty, tonsil operations.

There are several ways of explaining this diversity of opinion. In the first place, those who operate mainly on adults, will have more bleeding cases than those whose work is confined chiefly to children. Secondly, what by one man would be considered an alarming bleeding, would be regarded by another operator as a necessary incident of the operation. Thirdly, hemorrhage cases are not by any means always fatal, and often escape the notice of the operator. He perhaps notes that the patient is very pale for several weeks following the operation, but the true cause is not suspected.

Why one case bleeds and another does not is a perplexing question. One thing is certain, however, and that is that the bleeding is not necessarily due to excessive trauma or careless cutting of the constrictor muscle. In practically all of the cases we have seen, which number about one hundred, the bleeding has occurred following easy operations where the tonsillar fossae and pillars of the palate remained entirely intact. A possible explanation, which we have been unable to verify, is this: there is often noted in the fossa after removing a tonsil, a plexus of small veins due possibly to chronic inflammation. It is possible to conceive of the knife or snare splitting open one of these veins longitudinally so that in the movements of the throat, the forming clot is continuously expelled from the remaining part of the vein, and bleeding is produced.

Be this as it may, it seems to us that the bleeding is more often venous than arterial. Small arteries which are seen pumping in a throat just after removing the tonsil, usually cease bleeding in a few minutes and do not require ligating.

The dangerous type of bleeding, the kind which goes on to exsanguination and death, may be described as an ooze. This continues for hours without giving any of the test-book symptoms of hemorrhage. The blood may be expelled by coughing, but the half-conscious patient more often swallows it. Accordingly, unless vomiting occurs, hemorrhage may continue without the slightest evidence. We have recently seen such a case in which the nurse, of more than average experience, did not detect bleeding until ten hours after operation. She noticed that the patient, a child, swallowed frequently, but not until a large quantity of blood was expelled from the stomach did she realize the danger.

This, then, is an alarming situation. If we wait for the marked symptoms of hemorrhage, our patient's condition is very serious, and we should occasionally have a fatality. Such a condition is absolutely unwarranted. Death from hemorrhage ought never to occur. We believe that safety from this danger lies in a careful

inspection of the patient's throat at intervals after operation. Although such inspection may not disclose the actual bleeding point, owing, in the first place to the obvious difficulties in the way of obtaining a good view of a semi-conscious patient's throat, and secondly, the fact that the bleeding may be low in the fossa and thus escape detection, there is one sign which is unfailing in these cases, and that is a clot which forms in the fossa above the bleeding point. This clot is always present, and its presence is sufficient evidence of bleeding. When removed it quickly reforms. This danger signal appears at the beginning of the bleeding, and not as most signs do, when death is near. By careful observation of the throat and an early detection of the clot, we are enabled to deal immediately with the situation. We do not wait for other signs, but at once reapply our ether, and suture the pillars. This process takes about three minutes, and as but little blood is lost, the patient's recovery proceeds in the usual manner.

XV.

POLIOMYELITIS. OPERATIVE TREATMENT.

BY ROBERT SOUTTER, M.D.

Most of the cases of poliomyelitis fortunately can be helped by simple means such as active and passive exercises and massage, muscle training, temporary braces, mechanical stretching etc. The many cases that require operation form but a small group when compared to the total number of cases treated by other methods. Where simple methods of treatment are not sufficient muscle and tendon transplantation are often of great value.

Nicolodoni was the first to introduce this method in the treatment of poliomyelitis. Since then many operations have been devised to supplant and improve muscle and tendon transference so that today the cripple can not only be relieved of his deformity but many useful operations have been originated and developed which aid in his locomotion.

The relief of deformity is important and must not be lost sight of. Operations for the increase of function should next be considered. These operations are applicable to all cases of misdirected muscular action, whether due to trauma, to cerebral paralysis, to paraplegia, to poliomyelitis or to congenital deformities. Some of these operations of temporary value are done to allow the weak or partially paralyzed muscle to regain its strength or to prevent deformity and contractures during the process. Skin flap and silk ligaments are operations of this class. The value of an operation in poliomyelitis may be better understood if we group the types of cases according to the paralysis remaining. Omiting those cases that recover completely from their temporary paralysis we have five classes; Those that may obtain a return of function by muscle training; those where a restoration of joint balance requires a redistribution of the muscles by a tendon or muscle transference; Those where the balance is so upset that a transference, while it may take up the lacking motion and lacking antagonism, is not sufficient to keep a lateral balance. In this type silk ligaments, astragaectomies, arthrodesis or other operations may be used. Again we have a class in which there are muscles not paralyzed but not of sufficient number or strength to allow a division and transfer. In this type the joint may be balanced by silk ligaments and the remaining muscles become useful in part or the whole of their arc of motion. Today even when the paralysis is complete about a joint much may be done by skin flap, periosteal flap, silk ligaments or some other plastic operation such as arthrodesis or in the case of an ankle, astragalectomy.

The material we work with in poliomyelitis is often so poor that it is really remarkable to get the results we do. The trophic disturbance is often such that healing and firm union of the soft tissues takes much longer; resistance to infection is less, the slightest pressure during healing affects the result, poor approximation of the tissues is paid for by very slow, granulating wounds, the latter may remain granulating for weeks and then heal, all the time inviting infection. While infection is not common, the most scrupulous care in detail is required of these cases and more precautions are necessary than in the usual operation. The incision should be as small and vertical as possible and made with care, both as to the manner of penetrating the skin layer and as to the direction of the vessels.

In the early years of transplantation there were many failures and some that seemed good at first later were not satisfactory. This was accounted for by the fact that a tendon to tendon transfer was the rule. The good tendon stretched out the weak insertion and the power of motion became lost. Tendinous insertion is preferable where it may be done. This method is advocated by Vulpius. Periosteal insertion obviates many of our difficulties. Since the introduction of silk as a tendon by Lange in 1902 this method of tendon elongation with its periosteal, sub-periosteal and even bone attachment has relieved the cause of many of the previous failures. The silk acts as a good tendon and about it a firm cylinder of fibrous tissue forms which re-enforces the silk and acts as a tendon in itself. There are few operations where technique is of more importance than in tendon or muscle transference and silk ligaments. The action of the muscles must be well understood and carefully tested; the operation

studied and laid out for each individual case, the line of pull made as direct as the desired motion requires. With care the belly of a muscle may be transferred some distance. The muscle selected should be strong. Weak, degenerated muscles ought not to be transferred as they simply bring discredit to a procedure that is good and helpful. The attachment should be firm, not likely to slip or pull out. The silk itself should be tested before use and in situ, the limb put in such a position and the transferred muscles so placed that there will be no slack to mar the results. Muscles too weak to take up fully the desired motion may be transferred exceptionally for locking a joint. For instance, the tranfer of two weak hamstrings, although not sufficiently strong to extend the lower leg, may be sufficient to lock the knee in walking and standing and allow a certain amount of flexion in sitting. Paralyzed muscles should not be used for this purpose on account of their almost endless tendency to stretch out. Beside the many and varied muscles that may be transferred the following muscles, when large and vigorous, give pretty uniform success when transplanted, the pronator-radii-teres, the flexors and extensors of the fingers, the hamstrings forward, the peronei, the sartorius, the long flexors and extensors of the toes, the tibialis posticus and anticus.

The opponents of the muscle to be transferred should be carefully considered and balanced. In other words, a small, weak, transferred muscle should not be expected to be of value when opposed to a strong, healthy group. Enough must be transferred to give good balance.

The tranfer is more successful when the lateral stability of the joint is maintained by good muscles or by natural or artificial ligaments. The individual not interested in mechanics to a minute degree should not transfer muscles or endeavor to place silk ligaments but once the technique of the operation is well mastered a prolonged study of the single strong muscle in various extensively paralyzed cases will help more toward successful transplantation than any one other thing.

Since the introduction of astragalectomy the lateral stability of the ankle joint can always be obtained without stiffening the joint. This gives us one of the most valuable operations known in the treatment of paralyzed ankle muscles. It also gives us a method of obtaining the lateral stability where a transplantation is desired but otherwise impossible on account of lateral weakness. The cripple must be given a limb on which he can trust his weight. Misdirected muscular activity may be advantageously corrected by transplantation, which gives the desired motion; more should be done if alone this does not give a stable limb well balanced for weight bearing. In a child the calculation should be made for the probable future weight, both from natural growth and lack of activity. Silk ligaments may be used early to maintain position of the joint, later to maintain antagonism to existing muscles that unopposed would contract and cause deformity and themselves become useless. They may be used as an aid to stability of the joints as in toe drop combined with a lateral lack of stability. They are also of use to stiffen the joint. These ligaments should not be used to prevent a varus or valgus due to bony deformity where the weight is over balanced and out of line nor where the varus or valgus is due to the strong contracture of muscles. Except in these instances with proper technique silk ligaments give the greatest satisfaction to the patient and surgeon. Wherever silk is used crescentic incisions should be made and care taken to have several layers of tissue overlapping the silk insertion, the latter being placed under the flap some distance from the line of incision.

The after care of these cases is quite as important as the consideration before operation. Motion may be encouraged early under observation but strain in the early weeks must be prevented for two months by plaster and for six or eight more by suitable braces. After this, braces are used that allow motion but limit its arc. Silk ligaments and muscle and tendon transplantations, followed by careful after treatment and muscle training give us a most effective means of aiding the extensively paralyzed and deformed cripple. We can correct deformity, make up for loss of function, maintain corrected contractures and displacements and overcome much of the atrophy and do away with many braces. In all the severe cases a benefit can be expected and in many of the light cases a practical restoration of functional usefulness.

XVI.

The Importance of the Early Recognition of Acute Arthritis of the Hip-Joint in Infants.

By Arthur T. Legg, M.D.

The recognition of the presence of an acute septic process in the hip-joint in infants would seem to give very little difficulty, but the number of cases seen in which the condition during the acute stage was not recognized, shows that the importance of its early recognition cannot be too strongly emphasized.

The condition, as is well known, follows any of the acute infectious diseases, such as pneumonia, measles and scarlet fever, intestinal autoinfection or from a septic process elsewhere, and starts as an infectious synovitis or an epiphysitis which breaks through into the joint; and, as

in all acute infections of the joints, is characterized by limitation of motion, tenderness, thickening of the joint, and fever, with high white count.

The great difficulty in the early diagnosis comes from the fact that infants unable to express themselves can show only in a general way the location of any trouble, and the general intoxication, especially at this age, is so great that the local condition is often entirely masked.

Cases in which the condition has not been recognized are usually brought for advice on account of a limp noticed when the child began to walk, with a history of having had an acute abscess of the upper thigh accompanied by more or less prostration and high temperature, when an infant, the condition at the time having been considered a superficial abscess of the soft parts, which was simply incised or allowed to rupture spontaneously.

Examination of these cases will show a limp identical to that of a congenital dislocation, with a half inch to an inch shortening of one leg, and a cicatrix of the upper thigh, usually about the trochanter, where the abscess pointed or was incised.

Roentgenological examination of these cases will show dislocation of the affected hip with absence of the head and a portion if not the entire neck of the femur, showing that during the acute process, the head and a portion of the neck were destroyed by the septic process, and the abscess breaking through the capsule allowed the remaining upper end of the femur to dislocate; the abscess, after rupturing the capsule, pointing in the upper thigh.

In those cases seen soon after the onset, a common history given is that the apparently well infant became suddenly irritable, cried constantly when bathed, and had considerable prostration and fever; or if the condition comes on more acutely, the first symptom noticed may be a convulsion followed by symptoms typical to an acute meningitis.

Given these histories and symptoms, it is quite natural that a local condition in the hip is not at first considered, and these general symptoms may continue to predominate the local symptoms for some days and a diagnosis of a beginning acute infectious disease or an anterior poliomyelitis is often made.

It is not until after careful watching and a very complete physical examination is made that the true condition is recognized; and even this at times is most difficult in an irritable infant where all attempts at examination are resisted.

The classical symptoms as already mentioned, of local tenderness, limitation of motion, and thickening of the joint, are often masked by the general condition of the infant. As regards local tenderness, the infant may seem to be in pain when any part of the affected leg is touched, and no one region can be made to show more tenderness than another. While the affected hip usually shows more or less limitation of motion from spasm, motions of the unaffected hip may be equally resisted. To palpate joint thickening is at times very difficult, especially in an infant where there is much fat about the pelvis; but this can generally be made out if both trochanters are grasped and a careful comparison of the thickness is made. In some cases, the recognition of this joint thickening is the only positive means of recognizing the condition except by the roentgenogram. Examination by this method will show in the very early cases a markedly dilated joint capsule, with the head of the femur usually thrown out to the brim of the acetabulum; or, in cases which have gone on for some time, the head will be seen free in the joint or entirely disintegrated.

Just how soon the head will be freed from the neck of the femur or entirely destroyed by the septic process depends upon the severity of the infection and the mode of invasion. That is, those infections starting at the epiphyseal line will free the head more readily than those starting as an infectious synovitis; but that it may be freed very early is evidenced by the fact that in one case operated upon by the writer, the head was found free in the joint four days after the onset.

It is on account, therefore, of this early separation of the head from the shaft, followed by destruction and dislocation, that the early recognition of this condition is of the greatest importance, that immediate surgical interference may be instituted; for early incision and evacuation of the pus in the joint will in many cases save the femoral head, or if the head has already been freed or destroyed, dislocation of the remaining neck, by maintaining it in its normal position, may be prevented.

XVII.

THE DIAGNOSIS OF ENLARGED THYMUS AND THE SYMPTOMATOLOGY OF HYPER-THYMATISM.

BY PHILIP H. SYLVESTER, M.D.

THE diagnosis of enlarged thymus lies in finding it. The greatest difficulty in its diagnosis lies in not being on the lookout for it. The following cases are illustrative:—

CASE 1. W. B. C. Male, 14 months old; only child of well parents.

Past History. Full term, normal delivery, breast fed for six months, then on various mixtures. Always did well but has had a lot of colds. Has had no serious diseases.

Present Illness. Child had been "choking to death" for ten minutes after a cent, with which it had been playing, had disappeared.

Physical Examination. Well developed and nourished child in rather urgent dyspnea, cyanotic, inspiration slow, retraction of interspaces, supraclavicular and sub-sternal, expiration difficult as well. Ten teeth in good condition. Tonsils a little large, not inflamed, no particular enlargement of adenoids. Epiglottis altogether too small to have admitted a cent. Lungs full of coarse râles, some piping. Expiration a little prolonged. Heart not enlarged, sounds regular, good quality, rather rapid. Spleen not enlarged. No superficial glandular enlargement. Examination not otherwise notable.

The dyspnea being evidently of tracheal origin and not so urgent as to demand intubation or tracheotomy, a Roentgen photograph was taken with the idea that the cent had probably lodged in the esophagus in such a way as to press on the trachea. A large thymus was shown, but no cent.

(Photograph.)

The cent was found under the corner of the rug. A more careful physical examination showed a shield-shaped area of dullness to threshold percussion just below the clavicles and continuous with that of the heart, approximately 4 cm. to the left of the median line and 3 cm. to the right.

The child's mother, on further questioning, stated that the child had been having bronchitis for three or four weeks, during which time it had "choked up" on several occasions.

The child's dyspnea became more urgent that evening and on the following day he was admitted to a local hospital, where he received six Roentgen treatments of five minutes each at intervals of one week. In the first two weeks he was intubed twice for collapse in dyspnea. He was discharged, well, with no lung, tracheal, or thymic signs at the end of eight weeks.

This case taught me two lessons that have been valuable since:

1. To think of thymus in cases of infantile dyspnea suggesting laryngeal stenosis or obstruction.
2. To take more pains with the history even when in a great hurry.

Case 2. M. S. Female, 9 months, younger of two children. Parents well.

Past History. Full term, normal delivery, breast-fed for 5 months, then various mixtures; now getting about a 4.50—7—1.50—6 feedings 8 ounces. Is satisfied, never vomits. One movement is usually obtained daily by suppository or milk of magnesia; it is usually hard, brittle, very light colored and "smells very strong." The child has looked pasty since a short time after bottle feedings were begun.

Present Illness. Has been having bronchitis for six weeks, is better some days, worse others. Has had some rattling in chest all the time. Does not sit up much and does not try to talk. (Mother is also anxious about the teeth, as the persistence of the bronchitis has been ascribed by the family physician to teething.)

Physical Examination. A fairly developed, well nourished appearing but flabby child. Pasty color. Anterior fontanelle 1 inch by 1 inch, level. No teeth. Tonsils about the average, a little red. No snuffling or nasal obstruction. Ears negative. Lungs, good resonance throughout in back and front except that over upper portion of sternum and extending laterally is an area of dullness to threshold percussion 3½ cm. to the left of median line, 2½ cm. to right and connected by a fairly wide isthmus (vessels) with cardiac dullness below. Pressure on the inner ends of the clavicle, or over the manubrium causes an abnormal amount of tracheal compression. Lungs full of fine râles, mostly on expiration, which is prolonged as in ordinary asthma. Heart not enlarged, no murmurs, sounds good quality. Abdomen soft, contains a little more gas than usual. Liver not enlarged. Spleen not felt. No superficial glandular enlargement. Moderate rosary and slight enlargement of epiphyses of wrists and ankles. Physical examination otherwise not notable.

Diagnosis. Enlarged thymus, thymic asthma, rhachitis, fat over-feeding.

Subsequent History. Roentgenogram showed a shadow a trifle larger than the area of dullness, but corresponding so closely with it there could be no question as to the diagnosis.

The child received seven exposures of 5 minutes, at intervals of four days. After the fourth treatment I went away for two weeks and on my return the lungs were clear and there was no dullness other than that attributable to the large vessels. The mother stated that the child's breathing steadily improved after the second treatment. The child's appearance also improved greatly, but I am inclined to blame the correction of the food (to 2—6—2.50) for that as much as the involution of the thymus. There has been no recurrence of any symptoms referable to the thymus in two years.

Case 3. Clara M. Female, 22 months, youngest of five children. Parents well. No recent contagious diseases.

Past History. Full term, normal delivery, breast fed for 2 days only, then various modifications. Always did well as far as digestion and nutrition are concerned, but has been a little slow in mental development. Had measles very lightly at 14 months. Seems cold most of the time and gets blue when exposed to cold. Has had asthma most of the time for about a year. Attacks last some times over three or four weeks, during which the child gets quite blue. Has never had any "choking spells." Is seldom free from asthma for more than a few days at a time. Has not had many colds.

Present Illness. Has been having asthma for about two weeks with less remission than usual. Has become obviously tired. At times pulls on a chair or bed clothes to get her breath. Is losing weight. Has no appetite. Has not seemed feverish.

Physical Examination. Well developed, fairly nourished. Skin shows many fine wrinkles. Anterior fontanelle closed. Ears negative. Child in rather urgent asthma with prolonged expiration accompanied by wheezing. Twelve teeth. Tongue clear. Tonsils small, ragged, not inflamed; no apparent adenoid enlargement. Lungs, good resonance everywhere except that over upper sternum is an area of dullness to threshold percussion about the shape of the palm of the hand, extending 3 cm. to the right of mid-sternum and 3½ cm. to the left,

and about 5 cm. down, distinctly separated from the cardiac dullness. No D'Espigne's sign. Lungs everywhere full of bubbling râles on inspiration, which is short and gasping, and of piping as well as of bubbling râles during expiration, which is much prolonged. Heart not enlarged; action very rapid, no murmurs made out, quality good. Abdomen examination difficult as child refuses to relax. No enlargement of liver or spleen to percussion. No superficial glandular enlargement. Examination otherwise not notable.

Diagnosis. Thymic asthma.

Roentgenograph showed shadow about as on percussion, but apparently a little larger.

Child received five daily treatments of five minutes, then three of five minutes at intervals of four days. Was distinctly worse after first treatment, but began to improve after the second and continued to improve until the fifth treatment, when the asthma completely cleared up. Has had no further symptoms for nine months. Two weeks after the last treatment no thymus was noted by percussion. No plate was made at the last treatment, and the first plate is not now available for this paper.

CASE 4. T. T. Male, 19 months, only child, no miscarriages. Parents well.

Past History. "Eight months' baby," birth weight, 8 pounds. Breast fed for nine months, then whole milk and infant diet. Has had frequent colds. Tonsillitis several times. Otitis media on both sides at one year. Has looked pasty for about a year and does not seem as lively and bright as other children of same age in the neighborhood.

Present Illness. Cough and cold for about two weeks. Parents wish to have determined the cause of child's poor appearance; think his diet ought to be regulated.

Physical Examination. Well developed and nourished. Color, bluish white as in excessive fat feeding. (Later examination of stools showed nothing abnormal.) Anterior fontanelle admits tip of finger. Tongue clean. Throat red. Tonsils large and ragged, not inflamed. Pharyngeal wall studded with "warts." Adenoid visible when palate is raised. Ear drums wrinkled. No light reflex, no retraction, no fluid. Ten teeth. Lungs, uniformly good resonance except over sternum where to threshold percussion is a fat sausage-shaped area of dullness extending from mid-sternum to 4 cm. on the left and 3 cm. on the right, joining the cardiac dullness below. On crying, during expiration, a soft mass impinges on a finger tip hooked into supra-sternal notch. Inspiration short and easy; expiration prolonged with many râles just short of wheezing. Heart not enlarged, upper border not made out on account of thymic dullness. Sounds clear, no murmurs. Abdomen soft. Lower edge of liver just felt. Spleen 2 cm. below costal border, no notch felt. Genitals, phimosis, testicles undescended. Glands, lentil size in axillae, neck, and groins. Glands on right side of neck are larger than the rest, presumably due to infected tonsils. No abnormality of nervous reactions. Blood and urine not examined.

Diagnosis. Status lymphaticus; +thymic asthma seemed here unquestionable.

Unfortunately there was no Roentgen-ray apparatus within twenty miles, and the parents refused to send the child to the Children's Hospital for Roentgen diagnosis and treatment, in spite of my warnings as to the dangers of the condition. Six months later I learned that the child died without apparent cause while playing in his sand pile, previous to which he had coughed and wheezed a great deal.

CASE 5. E. T. Female. Five months old, youngest of three children. Family well. No contagious diseases.

Past History. Full term, normal delivery. Birth weight, 9¼ pounds. Is breast fed. Has had no digestive disturbance except for difficulty in nursing owing to the rapid breathing. Has gained slowly but consistently. Tends to be constipated; has always "breathed hard."

Present Illness. Comes for examination. Mother thinks child has growth in throat which has caused this hard breathing since birth. When nursing, the child cannot breathe through the nose, but sucks once or twice, then gasps for breath, breathes rapidly three or four times, then sucks once or twice, and so on. Has never been blue, but has wheezed of late.

Physical Examination. Well developed and nourished. Weight, 14 pounds, 4 ounces. Breathes quietly when undisturbed, but with distinctly more expiratory sound than is usually heard. When handled or disturbed breathes much more rapidly and noisily, especially during expiration. No wheeze noted. Anterior fontanelle three-fourths by one-half inch, level. Ears negative. No teeth. Throat not red. Tonsils not unusually large. Small adenoid felt. (No obstruction.) Lungs, good resonance throughout except in region of upper sternum, where there is a shield-shaped area of dullness to percussion (ordinary) extending 3 cm. to the right of mid-sternum and 2½ to left, and continuing down into area of cardiac dullness.

Pressure over supra-sternal notch and over manubrium increases the harsh sound of breathing. Lungs have few râles. Expiration is harsh, prolonged and high pitched with coarse moist râles, no piping râles and no wheezing, but type of breathing is asthmatic without the wheeze. Heart not enlarged. Sounds rapid, good quality, no murmurs. Abdomen, liver edge just felt. Spleen not felt. No general superficial glandular enlargement. Genitals negative. Physical examination otherwise not notable.

Roentgenogram showed enlarged thymus corresponding closely to area of dullness but more rectangular, relations pretty much the same.

Subsequent History. Received four exposures of 5 minutes on succeeding days. Seemed much worse after the first treatment, but symptoms were practically clear after the fourth exposure. Two weeks later no enlargement could be made out by threshold percussion. Child remained free of symptoms and gained well for four months, when breathing became again asthmatic in type, but not bad. Parents then, without consulting me, had given three treatments of 10 minutes each, three days apart. Two weeks after that I saw the child during a slight digestive upset and could find no trace of thymus or suggestion of asthmatic breathing. The child has remained well since.

The following case kindly reported to me by a colleague I add as an illustration of how easy it is to overlook an enlarged thymus, probably because we do not think of it, in the presence of dyspnea with symptoms of tracheal stenosis, and (as we usually do) make a diagnosis of laryngeal diphtheria. In this case an early diagnosis and Roentgen ray treatment might have saved the child.

Case 6. C. L. Male, 3 years, American.

Family History and Past History. Negative.

Present Illness. Past two weeks abscess in left cervical region; abscess opened by doctor and child getting well. Seen this evening at 6 p.m. and child had a hearty supper, seemed perfectly well and happy. At 7 p.m. child vomited and began to breathe hard and exude froth from mouth. About 9 p.m. child became worse, breathing very difficult. At 11 p.m. child seen by doctor and sent to diphtheria ward of hospital with diagnosis of laryngeal diphtheria. Admitted to ward at 12, midnight.

Physical Examination. A well developed and nourished child, quiet and apathetic, preferring to lie on the side; somewhat cyanotic; breathing labored with gurgling noise on respiration, no crowing sound. Child talks clearly. Marked retraction, on inspiration, of the intercostal and supraclavicular spaces. Reflexes normal. Pupils equal and react. Skin clear. Slight enlargement of the cervical glands. Discharging sinus on left side of neck just below the tip of the mastoid. Throat shows a large pair of tonsils. Large amount of bloody foam comes up the pharynx on smallest instigation. No membrane.

Heart very rapid, sounds weak and stopping. Apex unable to make out. P_2 greater than A_2. No murmurs. Pulse rapid, easily compressible.

Lungs, dullness at both bases with diminished breathing, above the dullness there are coarse, bubbling râles.

Abdomen, liver large, 3 cm. below costal margin. Spleen not felt. Soft, tympanitic. Temperature 99(?). Respirations 50, pulse(?). Antitoxin ordered, 12,000.

Patient had just received an initial dose of antitoxin of 4000 units when he stopped breathing without warning. Artificial respiration done at once and 1-40 gr. strychnia s.c. given, but without avail. The child proceeded to throw out a lot of mucus from mouth and bloody fluid from nostrils and after three inspirations at long intervals, the child died, the heart having stopped long before the breathing at 12.45.

Autopsy performed the next day shows the following salient points:

1. Excessive free yellow fluid in both pleural cavities.

2. Both lungs congested, dark, and hard to the feel. On section it exudes bloody fluid and froth. Peribronchial and root of lungs lymph nodes much hypertrophied.

3. Heart normal.

4. Thymus large, extending from thyroid cartilage down along and covering the deep structures of the neck; both lobes completely cover both auricles of heart, the length and width of the thymus gland being approximately 12 x 5 respectively.

5. Liver larger than ordinary size, dark and congested. On cut section shows markings obliterated by much fluid, very edematous. Gall bladder large, engorged with gall.

6. Spleen good size, also dark and congested.

Perhaps I ought to describe what I speak of as "threshold percussion" in the above cases. It is performed as follows: The mother, or the nurse, sits in a chair backed up into a corner of a small, quiet room (the bathroom serves very well), holding the child in her lap, the child's head hanging over either thigh. The physician starts percussion well out on the chest with such light strokes that when the ear is within a few inches of the area under percussion only the faintest possible resonance is heard. As the finger is moved care is taken to keep the percussion stroke uniform. When sound disappears dullness begins. Unless done in a quiet room and upon a quiet child this method is valueless. I have found it particularly satisfactory in determining the right border of the heart in small children.

The above cases are too few to admit of any hard and fast conclusions, nevertheless it seems fair to assum that—

1. We should be more on the lookout for enlarged thymus in cases of asthma, persistent bronchitis, and laryngeal or tracheal stenosis.

2. Inasmuch as the percussion outlines corresponded so closely with those shown by the Roentgenograms, the enlarged thymus should be found on examination by the ordinary methods of physical diagnosis, of which threshold percussion is apparently accurate and satisfactory in the hands of one familiar with children.

3. Children showing enlarged thymus present two fairly uniform sets of respiratory symptoms:

a. Those due to pressure on the trachea, as shown by cyanosis, slow, labored breathing and supra-clavicular and sub-sternum retraction.

b. Those presumably due to toxemia or hyper-secretion of the thymus, namely, breathing of the asthmatic type characterized by fairly easy inspiration and long, difficult expiration, accompanied by râles.

4. Inasmuch as in all the cases treated the symptoms for which treatment was instituted disappeared when the physical evidences of enlarged thymus disappeared, there is a causal relationship between—

a. The enlarged thymus and the pressure symptoms.

b. The enlarged thymus and the asthmatic symptoms which were obviously not due to pressure, therefore probably due to hyper-secretion.

5. Pressure symptoms and toxic symptoms may be combined in the same case, but those of the toxic type are more constant.

XVIII.

THE TREATMENT OF CERVICAL ADENITIS IN CHILDREN.

BY W. E. LADD, M.D.

AT the present time there is no uniform method of treatment of tubercular vervical adenitis adopted by the profession at large. I am writing this paper with the hope that by provoking discussion and adding my experience to that of others we may help to establish more uniformity of treatment of this disease in the future.

The methods of treatment which demand our attention at present are: Open air and hygiene alone, hygiene combined with tuberculin and palliative surgery, with X-ray therapy, with heliotherapy, with palliative surgery and with radical surgery. It will be seen that in this list of treatments, hygiene by which is meant open air, nourishing food, etc., is agreed to almost universally, and there are undoubtedly a certain number of patients who get well under this form of treatment alone. But they will not all recover under this therapy and we must consider what form of treatment added to hygiene will give us the best results.

The merits of tuberculin combined with palliative surgery, by which is meant the opening and drainage of abscesses as they occur, has been talked of a good deal during the last few years and recommended by many. Among quite a large number of cases that I have seen during the past five or six years I have been able to observe several patients treated in this way for varying lengths of time. I have always been disappointed in the results and the persistence of sinuses and the continued necessity of frequent dressings. Nor has the improvement in general condition of the patient ever been very striking to me. Of course the patients that I have seen under tuberculin treatment are only those requiring surgical care so that I may get a false impression of its efficacy. However in reviewing an article written in January, 1912, by John B. Hawes, 2nd, who is certainly an ardent advocate of tuberculin and hygiene, I find he reports twenty-one cases of tubercular cervical adenitis in children with ten apparent cures after treatment averaging eleven months in duration. He includes in his apparent cures patients in whom most of the glands disappear and whose general condition has improved. Also I note that in these apparent cures, three patients had a few small glands and two had one broken down gland. It has been my experience that such cases usually get well with treatment of the portal of entry and hygiene and incision and drainage of the single broken down gland. But even if he has made ten cures by his system of treatment, out of twenty-one patients who would not have got well otherwise that is an average of less than 50%. With this small percentage in favorable cases the position of advocating such treatment in place of good surgery appears to me untenable as I shall try to show later. These results of Dr. Hawes have interested me particularly because he is dealing with presumably about the same class of patient that we see at the Children's Hospital and in the same climate and also because I have confidence in his knowledge of the tuberculin treatment.

With X-ray therapy my experience has been limited. I have never seen a case of extensive adenitis cured by this means. It seems to me that the principle upon which it is based is irrational: namely the stimulation of periglandular tissue which prevents the gland from breaking down, encroaches on it and eventually causes its calcification. It seems to me more logical to remove the tubercular glands than to shut them up within the body. In superficial broken down glands that are slow to heal I have occasionally found the X-ray of great value, three or four exposures sufficing to cause healing. Likewise a few treatments with the X-ray will sometimes cause healing of a sinus and make possible a clean dissection of the underlying glands. In the few cases in which I have done this though the dissection has been clean it has been difficult on account of the denseness of the periglandular connective tissue. My observations on X-ray therapy though limited have coincided more or less closely in the cases with superficial infections with those of men who have used this form of treatment extensively. Thus Tousey[2] states that the Roentgen ray hastens the healing of sinuses and of tubercular abscesses which have been opened. Iselin[3] considers extirpation of tubercular glands the best form of treatment when the glands are not broken down; when they are, however, he feels that he has had very good results with the X-ray in over two hundred cases.

Heliotherapy has its advocates and apparently has yielded many good results, but is available only for those patients in this community who have sufficient means to enable them to go to high altitudes. That is the value of the sun's rays as a direct therapeutic agent is largely lost at sea level.

With palliative surgery I regret to state, owing to force of circumstances, I have had more experience than with any other form of treatment. The cases which get well under this treatment are those with single superficial broken down glands and these sometimes promptly and sometimes only after long periods of time with comparatively frequent dressings irksome to both the surgeon and the patient. In patients who have more than one gland involved which is of course far more commonly the case, palliative surgery has nothing to recommend it so far as I have ever been able to observe. In

* Read at the annual meeting of the New England Pediatric Society, December 12, 1913.

such cases the most superficial gland breaks down first, this is opened and about the time it begins to heal the next gland deeper in becomes fluctuant and requires incision. This succession of events continues until all the glands have broken down and been drained. Though the patient may eventually recover it is only after a period of months or even years and then with a neck presenting numerous and extremely unsightly and irregular scars.

What is the logical treatment for tuberculous infection of the cervical lymph nodes? We know from animal experimentation and perhaps more forcibly from the clever clinical experiments of Goodale[4], who injected coloring matter into the crypts of the tonsil and recovered it in the cervical glands, that we have to do with a descending infection. This infection has for its common portal of entry the tonsil, though we know from the experiments and observations of Stark[5] and Cornet that carious teeth may be the site of the primary focus. From other observers we find that the adenoid, the ear and the nose may though more rarely be guilty of harboring the primary infection. With these numerous sites through which the tubercle bacilli may gain entrance to the cervical glands it is not always easy to find which one is the portal of entry, but our knowledge of the distribution of lymph vessels makes it possible to avoid making many mistakes. Thus we know, for example, that the glands under the angle of the jaw drain the tonsil, the submental group the teeth and the anterior chamber of the nose etc.

Fortunately the glands most commonly infected are those in the superior carotid triangle under the angle of the jaw, and these are the glands which drain the tonsil. In these cases the tonsils should always be removed regardless of their appearance. I was surprised to find in an article by Judd[6] reporting several hundred cases from the Mayo clinic that he was able to trace the portal of entry in very few cases. He found that less than one per cent. of the tonsils examined had tubercular lesions. In my own series of forty dissections of the neck I have had the tonsils examined in sixteen cases. I am indebted to Dr. H. W. Karsner of the Pathological department of the Harvard Medical School for examining these with much care and for his report which now follows.

Histologically, unquestionable tuberculosis was found in ten of the 16 cases examined, or in 62.5%.

Grossly, the tuberculous tonsils with one exception failed to show any evidence of tuberculosis; the one exception (H. 13-233) showing in cross section numerous small yellow apparently necrotic areas, but nothing on the outer surface. The tubercles found histologically in this case were very distinctly caseous. Throughout the series the tubercles were either miliary or very small conglomerations, three cases showing no noticeable caseation, five only very slight caseation and two well marked caseation. Of the last, as indicated, one was sufficiently marked to be seen grossly in cross section, the other was not noticeable to the naked eye. The number of tubercles was either great or small, the tonsils being divided in this respect, five showing only a small number, five a great number. This point is of little significance for the results represent the picture as seen in only a few slides of each case; serial section might easily have produced a different picture. The same source of error is found in an attempt to group the cases according to situation of the lesions. From the examination of the slides, however, it was found that four cases showed a deep situation of the tubercles, *i.e.*, near the deep capsule, three showed a distinctly superficial position, *i. e.*, near the surface epithelium, and three cases showed wide spread diffusion of the tubercles. Giant cells, for the most part were frequent and typical, although in three cases they were in relatively small numbers, but, nevertheless, quite typical in morphology. The following table indicates the results:—

TABLE I.

FINDINGS IN REFERENCE TO TUBERCULOSIS.

	Position of Tubercles.			Number.		Giant Cells.		Caseation.*	Gross Evidence
Case.	Deep.	Superficial.	Widespread.	Few.	Many.	Few.	Many.		of Tuberculosis
11-1230			+		+		+	+	—
12-20		+		+			+	—	—
12-829			+		+	+		—	—
12-913		+		+			+	v. s.	—
13-103	+			+			+	v. s.	—
13-233	+				+		+	+	+
13-147	+			+		+		—	—
13-250		+			+		+	v. s.	—
13-289	+			+		+		v. s.	—
13-390			+		+		+	v. s.	—

* V. S. indicates a very small amount of caseation, — indicates a practically negligible amount of caseation, and + indicates well-marked caseation.

The tuberculous tonsils showed pathological changes in addition to the presence of the tuberculosis. Histologically, there was well marked retention in the crypts in four cases, slight retention in four cases and practically normal crypts in two cases. The follicles, particularly

germinal centres, showed slight hyperplasia in six cases, marked hyperplasia in two cases and were normal in three cases. There was moderate or well marked hyperplasia of the connective tissue in four cases, slight hyperplasia in two cases and a normal connective tissue in four cases. A review of the following table will show that of the ten cases, only one was normal aside from its tuberculous condition (13-399), two were only slightly diseased (13-829, 13-233) and the rest would have been considered distinctly pathological tonsils even had there been no tuberculosis present. Of the three only slightly diseased generally, two (13-399, 13-829) showed wide-spread tuberculosis and the third very well marked tuberculous involvement. It can not be said that there is any parallel between the degree of tuberculosis and accessory involvement. The table follows:—

TABLE II.

NON-TUBERCULOUS CHANGES IN TUBERCULOUS TONSILS.

Case.	Consistence.	Follicular Hyperplasia.	Retention in Crypts.	Connective Tissue Hyperplasia
11-1230	Soft	Slight	Slight	Moderate
12-20	Soft	Slight	Marked	Moderate
13-829	Firm	—	—	Slight
12-913	Normal	—	Slight	Slight
13-103	Soft	Marked	Moderate	—
13-233	Soft	Slight	Slight	—
13-147	Soft	Slight	Marked	Well marked
13-250	Normal	Slight	Marked	—
13-289	Normal	Slight	Slight	Well marked
13-399	Normal	—	—	—

The so-called non-tuberculous cases include those in which the few sections made failed to demonstrate histological tubercles. It is possible that serial sections might have shown tubercles and it is further possible that injections into guinea-pigs might have revealed the presence of tubercle bacilli in the tonsils. Of these cases, however, only one showed tonsils that were normal. The others showed various alterations, which singly or collectively stamped the organs as pathological. These changes are indicated in the following table. One case (13-193) was thought on gross examination to be tuberculous because the cross section of the enlarged organ showed numerous small yellow neurotic areas, but histologically these were found to be markedly distended and cystic crypts. The table follows:

TABLE III.

HISTOLOGICALLY NON-TUBERCULOUS TONSILS.

Case.	Consistence.	Follicular Hyperplasia.	Retention in Crypts.	Connective Tissue Hyperplasia
12-451	No Note	—	—	—
12-570	" "	Moderate	—	Marked
12-60	" "	Marked	Marked	Marked
13-135	" "	Moderate	Marked	—
13-215	" "	Moderate	Marked	Moderate
13-193	" "	Slight	Very marked	Slight

To summarize, it may be said that of the sixteen cases studied, only one (12-451) presented normal tonsils. Of five others, which were tuberculous, four showed sufficient retention of necrotic material in the crypts to regard them as seriously diseased tonsils. Of the ten tuberculous tonsils, all were regarded as seriously diseased because of the presence of tuberculosis and of these, seven were sufficiently diseased otherwise to justify removal.

The gross examination of the tuberculous tonsils showed nothing characteristic except in one case and the gross appearance of this case (13-233) was not sufficiently distinctive to differentiate it grossly from the appearance of a non-tuberculous tonsil (13-193) in which distention of the crypts produced yellow caseous areas in the cross section.

The tuberculous process in the involved tonsils was active and in no case was there found any attempt at encapsulation, although in two cases (12-829, 13-147) the large number of epithelioid cells and almost complete absence of necrosis gave rise to the belief that the tubercles were growing in a somewhat resistant tissue.

As far as can be concluded from the limited number of cases studied, 62.5% of cases of tuberculous cervical lymphadenitis show active tuberculosis of the tonsils. Of the remaining 37.5%, or six cases, five, or 83.3% of the non-tuberculous cases, showed pathological alteration, sufficient to justify removal, especially when it is considered that the presence of a low grade chronic inflammation may favor infection. Hence, had these tonsils remained they might have been a serious menace to the patient because of the danger of subsequent infection by a variety of organisms, including the tubercle bacillus. That these patients might be consid-

ered immune to tuberculous infection because of the attack of tuberculous cervical lymphadenitis, successfully combated by surgical removal, is not borne out by immunological studies of the disease.

These findings bring out two facts very clearly to my mind. First that there are many tubercular tonsils, which can not be diagnosed by inspection of the throat, and consequently the recommendation we hear so often made that in cases of cervical adenitis the throat be only examined is not to be commended. The tonsils should be removed as a matter of routine. Second that if anyone is still so misguided as to recommend a guillotine operation without the removal of the capsule he will probably leave the primary focus of tuberculosis in the throat. It will be seen from these facts that the first step in the treatment is the removal of the primary focus. After this has been done the question arises of how extensive a dissection of the neck is required. I feel that there has been a good deal of misunderstanding by the use of the term radical. A radical operation in the neck means to many physicians an enormous incision extending from the tip of the mastoid down to the middle of the clavicle and across to the sternal notch with the removal of all glands and gland-bearing structures underneath. I have seen such dissections dexterously performed without the removal of the tonsils followed by recurrence of the glands within three months. I do not consider such an operation radical in the true sense of the word which really means the destruction of the disease with its root. Any operation which omits the primary focus is not radical no matter how extensive. A radical operation can be performed through a small incision leaving an inconspicuous scar in the majority of cases. The incision of choice is a transverse one made in one of the natural creases of the neck as recommended by Dowd[7]. Through such an incision the whole of the superior carotid triangle can be reached easily and a part of the inferior and occipital triangles. Where the glandular involvement is very extensive the large incision is essential. This however is not very often required.

With a logical operation what results can we offer the sufferers of this form of tuberculosis? Dowd reports statistics on two hundred and seventy-five cases of which number fifty-four observed for from five to thirteen and a half years 98% were apparently cured. Forty-two observed for from three to five years 88% apparently cured. Eighty-seven patients observed for from one to three years 83.8% apparently cured. Ninety-two patients observed less than one year 85.8% were apparently cured. Of the total two hundred and seventy-five patients approximately 88% were apparently cured. He reports one death from a secondary hemorrhage from the internal jugular vein. Judd reports six hundred and forty-nine cases without any direct mortality but with one patient dying a few weeks after operation from general tuberculosis and one three months later from diffuse sepsis. Mitchell[8] reports similiar good results.

In my own small series of forty cases one patient died a few days after operation with symptoms suggesting meningitis. Of the remaining thirty-nine, thirty have been followed for periods of time from three months to two years. The other nine have been operated on too recently to suggest the probability of their cure. Of the thirty patients followed twenty-five are apparently cured by which I mean they show no signs of recurrence, no palpable glands and are in good general condition. These patients as a rule have improved very promptly in their general condition following operation. That is in a matter of about three weeks they begin to have a better appetite, put on flesh and improve in color, and do not need medical attention other than instructions about their mode of living. Of the other five not apparently cured, one shows no palpable glands but is in poor general condition though no site of disease has been discovered. Two patients had recurrences on the opposite side of the neck; one has a few small glands along the posterior border of the sterno-mastoid muscle, one has a small swelling in the scar. This gives in my series approximately 83% of apparent cures. I expect that some of these patients who are apparently cured now may have recurrences later and I expect to cure some permanently who now have recurrences so that the average will not be altered much. Of this series of cases of mine, only eleven have been operated on at a favorable time for operation, by which I mean before the glands had broken down or before sinuses had occurred. Of these eleven all the wounds healed by first intention. Nine have no recurrence. One has a few small glands along the posterior border of the sterno-mastoid and one has not had time to have recurrence.

With these facts in view I feel justified in drawing the following conclusions. That thorough extirpation of all infected glands with the primary focus yields by far the highest percentage of cures of any form of treatment yet devised.

That active tuberculosis of the tonsils in cases with cervical adenitis is probably far more common than has been supposed.

That to accomplish a cure by radical surgery requires far less time than by other means. This I believe to be a point of practical importance for although a child's time may be of small value, the time of the parent who brings the child may be of considerable value. To advocate the head of a family losing half a day a week for six months or more should be avoided when possible.

That to avoid unsightly scars and to insure first intention wounds the patients should be

operated on early before the glands have broken down.

That hygiene has a very important place in the after treatment and that the surgeon needs the cooperation of his medical brethren to help carry this out and to refer cases early.

The small size of the Children's Hospital has handicapped us considerably in the past by preventing our taking cases in promptly when the patients are in a favorable condition for operation. I hope that the new hospital will remedy this situation in part and I expect two years from now to report far better results than at present.

XIX.

A CASE OF LYMPH CYST OF THE MESENTERY.

BY CHARLES G. MIXTER, M. D.

The rarity with which cysts of the mesentery are met with at operation and the scarcity of accurate reports in the literature, with a careful analysis of the contents of the cyst and a microscopic examination of its wall, indicate the importance of reporting individual cases of this disease.

CATHERINE DONOVAN. Age, 4½ years. Jan 15, 1913.

Complaint. Swelling of abdomen for one month.

Family History. Father died three years ago of apoplexy. Mother and four brothers living and well.

Past History. Full term, normal delivery, breast fed 9 months. No known exposure to tuberculosis. Measles at one year. Otherwise well. Appetite good, bowels normal.

Present Illness. Three weeks ago mother noticed that abdomen was swollen and patient complained of discomfort. Given castor oil and diet was restricted without relief. Patient began to lose appetite. Child did not want to play. Abdomen gradually increased in size. No fever, no cough, no night sweats, no edema of face or legs, no vomiting or headache.

Personal Examination. Fairly developed and nourished girl, showing considerable loss of weight and pallor, breathing somewhat shallow. No glandular enlargement. Reflexes normal. Tonsils hypertrophied. Heart normal with the exception of somewhat rapid pulse, 110. Lungs showed signs of compressions at both bases, with slight dullness and with a few moist râles. Abdomen, tremendously large, symmetrical, dull throughout except for a small tympanitic area in epigastrium; 72 cm. in greatest circumference. No masses felt. Superficial abdominal veins distended. Blood examination: Hgb. 85%, white count 14,000. Von Pirquet reaction negative. Urine negative.

In spite of the fact that the Von Pirquet reaction was negative, a diagnosis of tubercular peritonitis was made and operation advised.

ETHER OPERATION.

Jan. 18, 1913. Two-inch right rectus incision near median line, peritoneal cavity opened with the escape of a small amount of free, straw colored, slightly cloudy fluid. The peritoneum was not thickened, no tubercles seen. On exploration of the abdomen a large, very thin walled, non-adherent lobulated cyst was found extending from the pelvis to the ensiform and filling the whole of the abdominal cavity. As the point of origin of the cyst could not be found on account of its size, the cyst was tapped and the greater portion of the fluid was withdrawn. Three quarts of fluid were saved, another quart or more being lost. Fluid was greenish yellow with a large amount of flocculent material and a number of clots which appeared to be fibrin, greenish yellow in color, the largest being the size of an English walnut. The wound was then enlarged and the cyst wall delivered, and it was found to arise from the mesentery beneath the first portion of the jejunum. The cyst grew laterally from either side of the mesentery and formed three lobes, two on the superior side of the mesentery and one on the inferior, the latter being the larger. The lobes of the cyst when distended with fluid lay closely approximated and the loop of jejunum beneath which the tumor arose, lay flattened out at the bottom of the sulcus. The intestine lay directly on the cyst wall, from which it could not be separated, and the only method deemed advisable was resection of the overlying loop of jejunum. Intestinal clamps were placed on the intestine on either side of the cyst, the mesentery beneath and on either side of the cyst was tied off in sections, and the cyst together with about eight inches of the adherent jejunum, was resected. A lateral anastamosis was done between the proximal and distal ends of the jejunum. The V-shaped gap in the mesentery was closed with catgut. A num-

* Read at the meeting of the New England Pediatric Society.

ber of enlarged glands were found in the mesentery, one of which was excised for microscopical examination. The abdominal wound was closed in layers without drainage and the child was put to bed in fair condition.

The patient recovered well from the operation but for six days was unable to retain any nourishment. Small amounts of liquids given by mouth might be retained for a number of hours and then the whole amount of nourishment given would be vomited in an explosive manner. No relief was obtained from gastric lavage. Bile was noticed in the vomitus. During this time she was given nutrient enemata every three hours, consisting of three ounces of peptonized milk and one dram of brandy, which were retained and absorbed remarkably well. X-rays were taken of bismuth given by stomach tube, and a dilated stomach and duodenum was found, with an apparently complete obstruction at the lower end of the duodenum, no food passing this point 48 hours after the meal was given. The temperature remained nearly normal. The pulse ranged about 90 until the fifth day after operation, when it rose to 120 and became intermittent. On Jan. 24 a further operation was deemed necessary to relieve the obstruction at the lateral anastomosis.

ETHER OPERATION.

Jan 24. Four-inch left rectus incision near the median line from the costal margin downward was made. No free fluid or indication of peritonitis was found. The omentum and transverse colon were lifted up, after freeing a small tag from the first operative wound. On investigation, the small intestine was found to have been rotated on its mesentery so that the body of the small intestine was found to lie chiefly in the upper right quadrant of the abdomen with a torsion of the mesentery to the right. The iliocecal valve was found on the left side of the abdomen just below the umbilicus. The pull on the superior vessels of the mesentery was sufficient to cause considerable obstruction to the circulation and tension on the anastomosis which had been made at the previous operation. The intestine at this point was thickened, plum colored, and the sitches, which had so far held without leakage, were beginning to pull through the coats of the intestine and on manipulation of the anastomosis the sutures gave way, leaving a large opening into the lumen of the intestine. The anastomosis was protected with gauze and the small intestine replaced in its normal position. An attempt was made to close the wound in the anastomosis but the stitches tore through the friable intestinal coats. Clamps were then applied, and the anastomosis and about one inch of intestine on either side was resected and an end-to-end anastomosis done, as it was found that the upper end of the jejunum was too short to permit of a lateral. As there was some doubt of the patency of the opening on account of the infolding of a large amount of tissue at the point of anastomosis, the small intestine was opened below the point of suture and a half length forceps passed upward through the anastomosis, which was found to be patent. The opening in the intestinal wall was then closed. The intestine in the region of the union was of normal color, showing that the circulation was no longer impeded. The abdominal wound was then closed in layers, without drainage.

Following operation there was some vomiting for four days, but at no time did the quantity of vomitus equal the total of liquids ingested. Bile no longer appeared in the vomitus. Nutrient enemata were continued at increasing intervals for one week, at which time they were omitted. Soft solid diet was given at the end of a week. House diet with care after the tenth day. There was some superficial suppuration in both wounds. A series of bismuth x-rays were taken three and one-half weeks after the second operation and showed the bismuth remaining in the stomach for an abnormally long time, apparently due to spasm at the pylorus, as there was none in the duodenum after nine and one-half hours. The bismuth was then expelled rapidly from the stomach and met with no obstruction in the small intestine. The patient made a rapid convalescence with steady increase in weight and was discharged to Wellesley convalescent home, Feb. 19.

She remained at Wellesley until April 9, and during this time only vomited once, on March 14, a small amount of thin yellowish fluid. Her weight increased from 27 pounds on March 7 to 35 pounds on April 9.

On Jan. 10, 1914, a report received from the mother of the child states that the patient is in excellent general health, has gained normally in weight and plays actively with other children; no digestive disturbances or trouble with the bowels were mentioned.

The following pathological report was made by Dr. W. F. Whitney, Harvard Medical School.

The specimen consisted of a cyst from the mesentery. It contained a large amount of fluid of a slightly yellowish opalescent color, specific gravity 1017, with spontaneous coagulum of fibrin.

Microscopical examination showed an occasional round cell. The wall was smooth externally, and internally it was trabeculated and smooth. The cyst was divided by an adherent piece of intestine into an hour-glass shaped sac, the two parts communicating by a small opening.

Microscopic examination showed in the wall numerous dilated passages, some with a fibrinous coagulum and others empty. The wall was composed of fibrous tissues, here and there with a little fat and lymphoid tissue interspersed.

The points of especial interest in this case were: First—the rapid increase in size of the cyst to its really enormous proportions; second—the absence of symptoms with the exception of those of pressure upward upon the diaphram; third—the transposition of the small intestine which had apparently been caused by the downward growth of the large inferior lobe of the cyst causing a torsion of the mesentery and rotation of the small intestine pulling the cecum across to the left side of the abdomen.

Mesenteric cysts were first noted at necropsy in the 17th century. The work of Arekion in 1891, Moynihan in 1897 and Dowd in 1900 was of importance in collecting the cases scattered throughout the literature and classifying them.

Moynihan classifies mesenteric cysts as—1. Dermoid, 2. Serous, 3. Chylous, 4. Sanguinous, 5. Hydatid, 6. Cysts of Adjoining Organs, 7. Cystic Malignant disease. He believes in the retention theory of their origin suggested by Virchow and supported by Rokitanski, that the

lympathics are occluded, and dilatation and cyst formations gradually take place. Chylous cysts occur by the occlusion of the chyle vessels or their rupture into pre-existing lymph or serous cyst. The sanguinous cysts arise in a similar manner. In a later paper he gives his opinion that many of these cysts develop from embryonic remains of the Wolffian bodies.

Dowd, on the other hand, believes that with the exception of hydatid and malignant cysts, all the cystic tumors of the mesentery arise from embryonic rests, derived from the Wolffian bodies. The doubt as to their origin is increased by the varied microscopical findings, for in the same specimen different loculi of a multiple cyst may be lined with different sorts of epithelium. A few cysts have been reported with endothelial linings and many, as in this case, present a wall composed simply of fibrous tissue.

The latest classification advanced by Child endeavors to clear up the meaning of the word mesenteric cyst. He contends that a dermoid should be classified as such whether it occurs in the ovary or mesentery or elsewhere. He excludes all forms of cysts from his classification except entero-cystomata which he believes are derived from Meckel's diverticuli and contain smooth muscle fibers in their walls; and cysts arising from the lymphatic system which may be lymphangiomata, simple, cystic, or cavernous, or chylous which are derived from the chyle vessels. It is probable that with the exception of hydatid and malignant cysts, mesenteric cysts, including dermoids, are of congenital origin. The latter arise from ectodermal inclusions. Others arise from embryonic rests of the Wolffian body or primary genital gland; another group are derived from Meckel's diverticuli; while still another class, of which this case is an example, take their origin from a congenital occlusion in the lymphatic system.

It is interesting to note that most of the serous cysts occur in the omentum, the intestinal edge of the mesentery, the mesocolon, and in the retroperitoneal region; while cysts which occur in the mesentery, except at the intestinal border, usually contain chyle.

Mesenteric cysts may be quiescent, to be revealed only at necropsy, or they may give rise to digestive disturbances of an acute or chronic obstructive nature. In their growth they fix the intestine and encroach upon its lumen by appropriating the mesentery to themselves, the bowel becoming flat and ribbon-like where it runs across the surface of the tumor. Pain may be caused by pressure on neighboring viscera or by secondary inflammatory changes.

In the early stage, the tumor lies near the median line in the upper abdomen and is more freely movable than other tumors in this region. Rapid increase in size may be caused by hemorrhages from the vessels of the wall into the cyst; or trauma without hemorrhage may produce a rapid enlargement.

There are four methods of procedure in the treatment of mesenteric cysts—1. Aspiration, which has been practically discarded on account of the large percentage of recurrence; 2. Enucleation, which can only be applied in a limited number of cases owing to the interference with the circulation of the intestine on removal of the cyst; 3. Marsupialization, or drainage of the cyst by stitching its wall to the anterior abdominal parietes; 4. Extirpation of the cyst with resection of the adherent intestine. The latter is the method of choice and though the statement made by Coley three years ago was a mortality of forty per cent., it is undoubtedly lower at the present time. Drainage of the cyst by connecting it with the abdominal wall is useful in cases where a radical removal is impossible or where there is severe infection. Treatment of cysts by this method does not lead to the establishment of permanent fistulae.

XX.

FLAT FOOT IN CHILDREN.

BY ALBERT EHRENFRIED, M.D.

A STUDY of the records of 1000 children under 12 years of age applying consecutively for treatment at the out-patient department of the Children's Hospital, in 1912, showed 440 having some static disability of the feet. These cases could readily be divided into three classes: congenital (18), idiopathic (95), and secondary (327.)

The 18 congenital cases, being the result of mechanical influences acting in utero, may be more properly classified with club foot. They belong to the type which I have described elsewhere[1] as potential calcaneo-valgus. In this condition the foot is not held fixed in the position of deformity, but it hangs flaccid in the normal position, assuming the position of extreme deformity on the application of very slight force, or even under the influence of gravity. This is the most frequent cause of delayed walking in children otherwise normal, which is explained by the fact that in this condition the child loses its ability to balance upon its feet. It is seen soon after birth and later; it is likely to lead to the most aggravated type of flat foot, and it sometimes requires operative treatment.

The secondary cases, which are by far the most numerous (327), include all those in which some primary causal factor is evident: rickets, represented by bow-legs, knock-knees, coxa vara, was present in approximately 200 cases, infantile paralysis in 107 cases, and tuberculosis of the knee, hemiplegia, lead, post-diphtheritic

[1] Ehrenfried: The Occurrence and Etiology of Club-foot, Jour. Amer. Med. Asso., vol. lix, p. 1940.

or spastic paralysis in 20 cases. In many of these the foot symptoms were of minor importance. In a considerable number, however, the diagnosis was not simple and the case was considered one of idiopathic flat foot until continued observation revealed the causal condition. In this inquiry no consideration was given to the type of flat foot, sometimes called traumatic, which arises as the result of wearing a plaster cast for a considerable time, or which occurs in a foot which is bearing the entire weight of the body, on account of disability of the other leg.

The third division, which may be called *idiopathic*, includes all the cases of weak, pronated, or flat feet for which no cause could be assigned, to the number of 95. Of these 52 were boys, of an average age of 6½ years, and 43 were girls, of an average age of 7 years. An examination of the history of these cases showed certain points in common. The condition was evidently due to insufficiency of the muscles supporting the arch of the foot, and was usually part of a general physical debility or lack of muscle tone. Some of the children were well nourished and otherwise in apparently good physical condition. A few were considerably over-weight, but it does not seem to me probable that weight alone, unless it be excessive, can be held responsible in these cases, for in a normal child increase in weight is met by a corresponding increase in power in the muscles of the leg. Bad shoeing must be ruled out in the majority of these cases, as the average child was too young to present marked symptoms from this cause. A considerable number showed evidence of other static disabilities, such as relaxed knees, round shoulders, functional scoliosis, protuberant abdomen, and gastroptosis.

Examination of the histories of 55 cases in which the records were full enough to be of value demonstrated that these 55 children, at an average age of 7 years, had had 147 diseases, including measles 30 times, whooping cough 24 times, chicken pox 11 times, tonsils or adenoid operation 10 times, pneumonia 8 times, scarlet fever, mumps, and glandular abscess each 7 times, bronchitis 5 times, chronic indigestion 4 times, otitis media 4 times, malaria, operation for hernia and appendicitis each 2 times, diphtheria, typhoid, phthisis, meningitis each once, and other conditions 20 times. One is at once struck by the multiplicity of the disorders from which these children suffered, and particularly by the frequency of the occurrence on this list of the infectious diseases, probably much above the average incidence in children at this age. Evidently these conditions are predisposing factors, and the obvious assumption is, that the child, being in poor physical condition as a result of repeated or long continued illness, suffers from a muscular insufficiency which is responsible for the static disability. Poor nutrition, without evidence of any definite illness, also accounts for a certain number of cases.

Attention may profitably be given to the *prophylaxis* of this condition. In the first place this requires regulation of the feeding in infancy and early childhood. Proprietary foods and other substitutes which may predispose to rickets should be carefully avoided in infancy, and later the diet should be well balanced, avoiding an excess of carbohydrates, and supplying plenty of proteids and fresh vegetables or fruit juices. In the second place the spread of infectious diseases and particularly of infantile paralysis, should be controlled so far as possible. This is a matter largely in the hands of boards of health and school and district physicians. Corrective shoeing and proper exercises will go far to prevent disability in children who are delicate, or weakened as the result of illness.

It is probably true that many cases of flat foot in adults have their inception in some condition of the foot which has been overlooked in childhood. *Treatment* should of course be started early, and the outlook for ultimate restoration of function is considerably better than in adult flat foot. Methods depend on the type.

The cases of potential calcaneo-valgus are brought in soon after birth, on account of the evident deformity, or not until 18 to 24 months, on account of delayed walking. Cases seen within the first few weeks respond as a rule very well to treatment by over-correction and retention in plaster of Paris for a few months. The older children are frequently difficult to treat. Mild cases get well with a tilted shoe and instep pad, worn for about two years. Bad cases need a brace, and may have to be operated. The brace I use is just the reverse of the one I have employed in the treatment of equino-varus,—it is a laced shoe which fits the foot, elevated on its inner border, with a jointed external upright, stopped to prevent dorsiflexion, and a T-strap on the inner side.

The treatment of foot disabilities secondary to other conditions, such as rickets and infantile paralysis, is the treatment of the underlying condition. When this has cleared up or is under control, or if the foot symptoms are the chief element, attention should be directed to their relief. In the paralytic foot muscle training is of great benefit, but operation by muscle transplantation or insertion of a silk ligament frequently becomes a necessity.

The cases of idiopathic flat foot as a rule are of a mild or moderate degree, and respond well to treatment, if carried out for a sufficient length of time. Metal plates should be avoided. Massage of the lower legs, exercises carried out persistently under supervision, the leather instep pad and the tilted shoe are usually adequate. Severe cases may require temporarily the brace which I have already described. The rigid feet and the exostoses of the adult are

not seen. Acute cases need rest in bed or fixation in plaster of Paris.

CONCLUSIONS.

First, the diagnosis of weak, pronated or flat foot should not be made inconsiderately. In 327 of the 440 cases the foot symptoms were secondary to some other condition, which required treatment. Continued observation in many apparently simple cases showed mild rickets or unsuspected infantile paralysis as a cause, and less frequently such conditions as tuberculosis of the knee, hemiplegia, or lead, post-diphtheritic or spastic paralysis.

Second, 18 of the primary cases were congenital. These, the result of mechanical influences prior to birth, are more properly classified with club foot; they belong to the type to which I have given the name of potential calcaneo-valgus.

Third, a study of the other primary cases, 95 in number, shows evidence of muscular insufficiency resulting from physical debility as the leading factor in causation. This debility, as shown by the records, is frequently the sequel of an infectious disease, and is particularly apparent when the child has been the victim of a series of infections in close succession. Other static disabilities, such as relaxed knees, functional scoliosis, and gastroptosis are likely to be present.

Fourth, the secondary cases, which were in the majority, were the result of rickets or of rhachitic deformities in approximately 200 cases, of infantile paralysis in 107, and of other conditions in approximately 20 cases. In many of these the foot disability was a minor incident.

Fifth, prophylaxis of foot disabilities consists in combating the two important causes therefor, rickets and the infectious diseases of childhood. Both of these should yield to hygiene. Measures to lessen substitute nursing of infants by means of proprietary foods or improper milk mixtures, and to control the spread of contagious diseases through schools, which, at the present time, are probably the chief agents in the dissemination of infections among children, will result in an important diminution in the incidence of these conditions.

Sixth, treatment is usually effective.

XXI.

PYELITIS IN INFANCY AND CHILDHOOD.

BY EDWIN T. WYMAN, M.D.

PYELITIS is not a rare disease in infancy and childhood, but it is a disease which may be easily overlooked without an examination of the urine in cases of obscure fever.

In the majority of cases there is nothing whatever in the symptomatology to call attention to the urinary tract, the symptoms being merely an elevation of temperature and those common to all febrile disturbances in infancy, such as restlessness, fretfulness and signs of indefinite discomfort. Anorexia is the rule and vomiting is not unusual. The temperature is relapsing in type, often reaching 105°F.

In infants, the physical examination is usually negative, except that pallor is characteristically present. There may be tenderness in the lower abdomen, and in some instances the kidney is palpable, more often on the right than on the left. The spleen may be palpable at the onset of the disease.

In the vast majority of cases the diagnosis can only be made by examination of the urine. Consequently the urine should be examined in all diseased conditions in infancy with indefinite symptoms, especially if febrile, and no physical examination should be considered complete or diagnosis satisfactory in obscure conditions in infancy unless the urine has been examined. Not infrequently these cases of pyelitis are treated for other diseases and as spontaneous cure occurs in many of the acute cases, the presence of pyelitis is never recognized.

Pyelitis in infancy is often associated with more or less intestinal indigestion, and the infant is treated for this condition when the indigestion is really secondary to the pyelitis.

Sometimes the patients object to being handled; are very irritable, and have tenderness of the extremities resembling that in scorbutus. Other cases may have pain and tenderness in the abdomen and have even been operated on for appendicitis. The irregular temperature may suggest malaria or typhoid fever. Some cases may have marked symptoms resembling those in meningitis.

The following are two typical cases in which the diagnosis was overlooked:

CASE 1. Frank N. Age, 3 weeks. The family history was negative. He was a full term baby, and the delivery was normal. He weiged 10 pounds at birth, and at the age of 2 weeks he weighed 11 pounds. He was breast fed, and was a normal, healthy baby up to his present illness. One week before he was seen, he did not take his feedings as well as usual. The following day his temperature was normal in the morning and 100.2° F. in the evening. The next day he did not seem quite as well and his afternoon temperature was 104° F. He was thought to have indigestion and was given two teaspoonfuls of castor oil and an enema, with good result. During the next three days his condition grew worse. He was very irritable and his pallor increased. His temperature was irregular, 103° F. to 104° F. in the evening, and 101° F. to 102° F. in the morning. The temperature had never been normal since the onset. The bowels were constipated, the movements greenish, and contained a considerable number of small soft curds. There had been no vomiting and no convulsions. It had been noticed that the urine was "white like milk

and water." The breast milk was discontinued the day before he was seen and whey was given, with no improvement in symptoms.

Physical Examination. He was a well developed and nourished infant. The skin was clear but pale, and the muscles were flabby. The anterior fontanelle was 4 x 5 cm. and level. The ear drums were normal. The throat, mouth, heart, lungs, and abdomen showed nothing abnormal. The liver was palpable 2 cm. below the costal margin. The spleen and kidneys were not palpable. The extremities were normal.

Case 2. Mildred T. Age, 13 months. The family history was negative. She was born at full term, after an instrumental delivery. Her birth weight was 8 pounds. She had been breast fed up to the time she was seen and had always been a well, normal baby.

Ten days before she was seen she was taken suddenly sick with fever and chills, and she had a slight cough. The temperature had never been normal since the onset and had been irregular, sometimes reaching 105° F. She had grown more fretful and irritable every day and had lost considerable weight and a good deal of color. Her bowels had been regular and the movements were normal.

It had been noticed that the micturition had been frequent and painful. For two days before she was seen she vomited nearly every feeding, and for 24 hours before she was seen the vomiting seemed to be of a projectile type. The head had been retracted, and there had been rigor and slight twitching of the arms and legs. There had been no convulsions. She was thought to have meningitis.

Physical Examination. She was a well-developed and nourished, very sick looking little infant. She was very pale and flabby. She had evidently lost considerable weight. She was conscious, but very irritable. The head was held slightly retracted, but it could be easily flexed.

The anterior fontanelle was 2 x 3 cm. and level. The pupils were equal and reacted to light. The ears, mouth and throat were normal. The lips and tongue were dry and parched. There were eight teeth. There was no enlargement of the peripheral lymph nodes. The heart, lungs, abdomen and extremities were normal. There was no spasm or paralysis and no neck sign. The knee jerks were present and equal. There was no Kernig or contralateral reflex.

The urine in both these cases was acid and contained slight trace of albumen. The sediment showed many pus cells, free and in clumps, and many motile bacteria. The symptoms and fever in both these cases disappeared within two weeks, with the alkaline treatment, and the urine was nearly free from pus at the end of three weeks.

In a series of 65 cases of pyelitis in infants and children at The Children's Hospital, Boston, 54% were in infants under two years, and 46% were in children beyond two years. Of these cases 63% of the infants were females and 90% of the children were females. Vomiting was noted in 39% of the cases; painful micturition in 36%; and frequency of micturition in 40%. Chills were noted in 15%; and abdominal pain in 16% of the cases. The average leucocyte count in the uncomplicated cases was 19,000; the lowest leucocyte count was 8,000 in a chronic case; and the highest leucocyte count was 62,000 in a very acute case. The temperature varied from normal, in the chronic cases, to 105.5°F. in the acute cases. There was anorexia, anemia, fretfulness and loss of weight in all the cases.

Pyelitis occurred as a complication with other diseases in these 65 cases as follows:—Otitis media, eight times; pneumonia, seven times; infectious diarrhea, four times; bronchitis, twice; intestinal indigestion, twice; measles, twice; typhoid fever, twice; and tubercular peritonitis once.

Some of these cases yielded readily to treatment, the urine clearing up in two weeks; while other cases were more resistant and were only improved at the end of six weeks.

The organisms responsible for the infection in pyelitis, in a large proportion of the cases are the colon bacilli, although staphylococci, streptococci, and pneumococci are sometimes found.

The urine in pyelitis is pale, uniformly cloudy or turbid; the turbidity is due in part to the bacteriuria, and in part to the presence of large numbers of pus cells; chiefly to the latter. The reaction is almost invariably acid, not infrequently highly so, and there is a slight trace of albumen.

Microscopically the sediment is composed of many pus cells, free and in clumps, many motile bacteria and usually a few caudate, small round and squamous cells.

There are three possible modes of infection.

(1) *The Ascending Theory*: The chief arguments in favor of an ascending infection from the urethra are the much greater frequency of this condition in females, most common in diaper age, and the short wide urethra which makes infection easy when the external genitals are soiled by feces.

(2) *The Hematogenous Theory*: That the bacteria are borne to the kidney by the blood stream.

(3) *The Transparietal Theory:* That the bacteria are transmitted directly from the intestines to the kidney.

Morse writes[1] that in the majority of cases in girls, the infection is through the urethra, while this route is very unusual in boys, and then only when there is some evident lesion, such as phimosis causing stasis, severe balanitis, or an infected wound from circumcision. In most cases in boys and in a fair proportion of those in girls, the infection is probably transparietal, while in both sexes it is occasionally hematogenous[1].

PROGNOSIS.

There is practically no danger as to life. With treatment recovery usually occurs in a few weeks, but the condition may persist with intermissions for many months. In some instances

the urine contains bacteria and at times pus for years, although there is no constitutional disturbance. There is very little danger of the process extending to the kidney, or that it will involve anything more than the superficial layers of the pelvis and bladder.

The pathology shows simply a catarrhal condition of the bladder and pelvis of the kidney. Very few autopsies have been made, because the condition is rarely fatal.

TREATMENT.

The alkaline method of treatment will often suffice to cure the disease. Potassium citrate is given well diluted with water, grains X, three times a day for an infant one year old. If the dose is not sufficient to make the urine highly alkaline, larger doses must be given. Another line of treatment is to change the reaction of the urine every three or four days by first making the urine alkaline with potassium citrate, then acid, with sodium benzoate or benzoic acid in doses of grains iii, three times a day for an infant one year old. This changes the reaction of the media and discourages the growth of the bacteria.

If the urine does not clear up under this treatment, hexamethylenamin in doses of from one to three grains should be used. If the urine is alkaline, it should be made acid with sodium benzoate or benzoic acid. The urine should be tested for formaldehyde by Berman's[2] test and the hexamethlyenamin increased until the urine shows the presence of formaldehyde; the urine being carefully watched for irritation of the kidney.

If the trouble still continues, large doses of hexamethylenamin, aided by autogenous vaccines may be used as Freeman[3] advises, gradually increasing the hexamethylenamin to gr. 25 daily for an infant of six months and grains 25-45 a day for an infant of nine to 12 months. Vaccine should be given every three or four days, beginning with a dose of 25,000,000 and increasing to 160,000,000. The large doses of hexamethylenamin should not be continued for more than a week at a time, and then after several days without any treatment, or with alkaline treatment, the hexamethylenamin should be started again at the same maximum dose given before[4]. The urine should be carefully watched for irritation of the kidney.

Local treatment of the bladder is of comparatively no value, because the infection is not localized in the bladder but involves the whole urinary tract.

XXII.

TWO CASES OF CIRRHOSIS OF THE LIVER IN CHILDHOOD.

BY THEODORE ELY, M.D.

While cirrhosis of the liver in children is no longer regarded as an exceedingly rare condition, it is by no means a common one, and that type of cirrhosis which is due to alcohol may still be said to be a most unusual affliction in childhood.

The first case of this kind of which we have a record was reported by Wilks in 1863 before the Pathological Society of London (Pathological Society of London 1863, Vol. XIV.) In succeeding years occasional cases were reported from England, America and the Continent. Among a total of sixty-three reported cases of hepatic cirrhosis of various types R. Palmer Howard in 1887 found ten cases whose cause could be traced to the abuse of alcohol. (R. Palmer Howard in *American Journal of Medical Science*, Oct., 1887) *Haushalter and Richon in 1899 collected twenty cases from the literature. Of these only fourteen came to autopsy and the alcoholic cause of at least one seems very doubtful. In 1907 Bolton of London (Cirrhosis of the Liver in Children—*Clinical Journal*, London, 1907-08) reports that at the time seventy-four cases had been described in the literaturue. This would scarcely seem a sufficient number to agree with his further statements, that hepatic cirrhosis of some type is found in .2% of all autopsies on children under 12 years of age in England, and that England is noted for its frequency in alcoholic cirrhosis, or with the statistics of various authorities quoted by Rapin (These de Nancy, 1899, Contribution a L'Etude de la Cirrhoe Alcolique) among whom Hebrad traced the origin of seven out of fifty-one cases of hepatic cirrhosis and D'Epine and Picot seventeen out of one hundred to the abuse of alcohol, or with the opinion of Morse (BOSTON MEDICAL AND SURGICAL JOURNAL, Sept. 11, 1902) that alcohol is responsible for from ten to twenty-five per cent. of all cases in children. In a brief but fairly comprehensive review of the English literature since 1907 I have found only two cases reported in this country and but one of these was proved by autopsy to be of the alcoholic type. (Blakely, BOSTON MEDICAL AND SURGICAL JOURNAL, 1910) (Davis—Cirrhoin a Boy of two years—*West Virginia Medical Journal* 1912—12.)

The disease seems to be more common in boys than in girls. The youngest case on record I believe is about sixteen months of age. The average seems to be between eight and eleven years.

The symptoms differ somewhat from those found in the adult. Jaundice is a fairly common symptom in children. Epistaxis is as fre-

* Revue Mensuelle des Maladies de L'Enfance, Mar., 1899.

quent and diarrhoea and vomiting more so than in the adult. Haematamesis is less frequent in children but several cases where this was the immediate cause of death have been recorded. Enlargement of the spleen is practically constant in children as is the hypertrophy of the liver in the earlier stages of the disease. The enlargements of the liver is not only more constant in the early stages in children but often persists until death. Dilatation of the superficial abdominal veins is perhaps less common and slight elevation of temperature more common. Ascites and oedema are about as common but seem to appear relatively later in the course of the disease.

The nervous symptoms in children are confined to marked drowsiness and sometimes loss of speech. Peripheral neuritis, delirium tremens, etc., are practically never seen.

The course of the disease is much shorter than in adults. Complications aside from the embarrassed heart action seem rare and the children usually die of the progressive asthenia.

The pathological changes found at autopsy due to the disease *per se* are practically identical with those found in the adult cases except for the constant splenic enlargement.

The two instances of hepatic cirrhosis in children which I have the privilege of reporting to you were observed in a pair of twins, four years of age, first seen in the medical out-patient department of the Children's Hospital on Oct. 6, 1913, and subsequently observed in the medical wards there.

Case History, G. O.

Family History. Father and Mother living and (always have been well) well. Two sisters living and well. Another pair of twins, boys, at 2½ years, living and well. First child died from cholera infantum. Second pregnancy resulted in miscarriage at 3½ months. Fourth pregnancy which followed the birth of first living child also resulted in miscarriage at 3½ months. Neither father nor mother has had sore throat or rash. Both deny specific infection or constant use of alcohol.

Past History. Born instrumentally at full term. Has always been about 4 lbs. heavier than the other twin. His mother says that the infant was black for 24 hours after delivery but then regained normal color and had no paralysis. He was breast fed for 14 months. Had no acute infection until after onset of present illness. Ever since the breast feeding was stopped the mother has been in the habit of giving both children small amounts of brandy at frequent intervals. She started giving three drops every hour, but as the children have grown the dose has been increased until sometimes they have been given a half teacupful at a time. The mother estimates that the children have each had a quart of brandy on an average of at least 16 drops a day since fourteen months old. The father, who confesses to a "moderate" use of alcohol, tells of having found both boys drinking whiskey by the half-cupful when one morning he came unexpectedly into the dining room, where he had been entertaining a friend on the previous evening and had carelessly left a partly filled quart bottle of whiskey on the table. The mother states that the brandy which was first given in small doses because the infants "seemed puny and had no appetite" was later given in larger doses when the children had a toothache or a pain.

Present Illness. In January 1913 patient developed painful swelling on penis. One week later mother noticed yellowish tinge in sclera. Child developed a voracious appetite with constant desire to drink water. Skin gradually turned yellow and has been more or less so ever since. There was no vomiting at the onset. About two months after onset mother noticed the dark smoky red color of the urine and that it left a red stain on clothes. The stools since onset have averaged from 4 to 5 a day and have generally been clay colored and very foul smelling. For a while under medical treatment they became darker. In July last had a severe attack of measles, and for about a month the jaundiced color of skin disappeared, but the urine and stools retained the characteristics noted. For the past two months the abdomen has been growing larger and the rest of the body thinner and the skin has itched. In that period the gums and buccal mucosa have grown tender and bleed easily. Two weeks ago the mother found the patient's pillow and bed clothes covered with blood. No blood has ever been noticed in urine or stools. Two months ago swelling of fingers at the distal joints was noticed. He is now drowsy and sleeps all the time; no headache, digestion seems good, and he never vomits. Since attack of measles has lost considerable weight. Has never had any convulsions, fever, cough or sore throat. For a month before admission was kept on—fat and sugar—restricted diet without improvement. Child looks and acts drowsy.

Physical Examination. Patient is poorly nourished with little subcutaneous fat. Skin is dry and lax and uniformly jaundiced, rough and in spots excoriated from scratching. Petechial spots on arms and legs. Eyes show marked yellow sclera with reddened conjunctivae. Buccal and nasal mucosa reddened and congested and beneath the buccal and palatal mucosa small punctate hemorrhages are visible. The lips are excoriated and cracked. There is a general glandular enlargement. Heart: Boundaries on percussion are 2½ cm. from the right and 7 cm. from the left of the M. S. L. No abnormality of sounds. Lungs negative. Abdomen distended, convex. There is slight shifting dullness but no distinct fluid wave could be demonstrated. The superficial veins are prominent and somewhat distended. Liver dullness begins above at lower edge of 5th rib in nipple line on the right. The lower edge is distinctly palpable 5 cm. below the free costal border in the nipple line and 5 cm. below the tip of the xyphoid in the median line. The edge is smooth and not very tender. Spleen is much enlarged, the lower pole being palpable 7 cm. below the costal border and 4 cm. from the median line. No other abnormal masses palpable. Extremities show no edema. There is marked clubbing of the distal joints of the toes and fingers. Genitals show no edema. Urine was red, smoky, acid and con-

tained bile but no albumin or sugar. Stools were grayish yellow in color, contained bile, no blood, pus or mucous. Blood count showed nothing remarkable in numbers or character of white or red cells. The hemoglobin was 70% by Tallquist. Wassermann's complement fixation test and Von Pirquet skin test were both negative.

Ten days later on Oct. 16th the physical condition showed little change. Jaundice persisted. The boundaries of the heart, liver and spleen showed no appreciable change by percussion and palpation. The urine and stools both contained bile.

At the request of the parents he was discharged home from the hospital on Nov. 4th, four weeks after entrance. The jaundice was much less marked, as was yellowing of the sclera. The petechial spots on the arms and legs were fewer and the child was scratching much less. The area of cardiac dullness was unchanged. The spleen was felt in the same situation as before. The lower edge of the liver was palpable 3¼ cm. from the costal border in the right nipple line. The urine still contained bile but the reaction was less marked. During the child's stay in the hospital the pulse and respiratory rate ranged within normal limits. His evening temperature during twenty-nine days of observation reached 100 on eight evenings and his maximum was 101.6 reached on one evening. For the rest of the time the daily variations were within normal limits.

The patient was last seen alive on Dec. 9th. After leaving the hospital his condition showed little change until December 6th. The urine remained of reddish color. The stools were described as having grown more normal in character and no blood had been seen in them. Dec. 6th he began to vomit and retained practically no food after this. He coughed up and vomited blood at frequent intervals. The mother noticed that his breathing became more rapid and difficult. He complained of pain in the upper right quadrant of the abdomen which was somewhat relieved by rubbing. On examination his respirations were grunting and labored, rate was about 52 per min. The pulse was too rapid for count, poor volume and tension. The physical signs in lungs were those of consolidation of the right lung extending from the base upward in back to the upper angle of the scapula and in front to the third interspace. In the lower left axilla the breath sounds were much diminished and moist rales were numerous throughout. The left border of the heart was 8 cm. to the left and the right 4½ cm. to the right of the M. S. L. Because of the lung consolidation on the right it was impossible to make out the character of the cardio-hepatic angle or the upper limit of hepatic dullness. The heart action was very rapid but regular and no abnormality of sounds aside from their generally weak character was detected. The abdomen was enormously distended and showed the usual signs of free fluid. Superficial veins were very prominent on both abdomen and thorax. The liver was tender and its lower edge was indefinitely felt 2 cm. below the costal border in the nipple line. The lower pole of the spleen was distinctly felt 5½ cm. below the free costal border in the anterior axillary line. There was marked edema of the genitalia and slight edema of the extremities. Emaciation was more marked and the condition of the mouth worse than on leaving the hospital. The patient died at two o'clock the following morning.

CASE HISTORY, C. O.

Family History. The same as the other child.

Past History. Was delivered normally at full term. Except for having always been the smaller of the twins his past history is not important.

Present History. Began two weeks after the brother's. The first symptom noticed in January, 1913, was the yellowish discoloration of the sclera. The story of his present illness was exactly identical with his brother's except that his attack of measles last July was less severe than his brother's and jaundice has never disappeared. The character of stools and urine, jaundiced and itching skin, painful, easily bleeding gums and buccal mucosa, epistaxis and clubbing of fingers have all been the same as his brother's, and the last four symptoms have appeared at about the same time as the brother's. His abdomen has never grown so large as the brother's. He has never had convulsions or fever, cough or sore throat except with the measles.

Physical Examination. Much the same in its important points as the brother's. Sclera of the eyes is markedly yellow. The buccal mucosa shows punctate hemorrhages underneath, most numerous over the palate. Tonsils are large and fibrous. There is general glandular enlargement. The lungs give no abnormal physical signs. Cardiac dullness extends from 3 cm. to the right to 6 cm. to the left of the M. S. L. The sounds are somewhat irregular in rate and rhythm, the second pulmonic is much accentuated, no murmurs or friction sounds detected. The abdomen is distended, convex, and above the level of the thorax. The upper limit of hepatic dullness is in the 5th inter-space. The lower edge of the liver is smooth, firm, and easily palpable 5 cm. below the costal border in the nipple line and 4 cm. below the xyphoid. The lower pole of the spleen is palpable 7½ cm. below the costal border and 7 cm. from the median line. No free abdominal fluid detected. The superficial abdominal veins are prominent. The genitals show a moderate hydrocele of the right testicle and slight phimosis. The clubbing of the fingers and toes is marked, no edema of extremities, the reflexes are all normal.

The urine was slightly acid and contained bile but no albumin or sugar.

Stools yellow, formed and smooth, contained bile and no blood or pus.

The blood examination showed 5,500,000 red cells and 6,500 white cells per cubic mil. Of the white cells 55% were polynuclears and 45% of the mononuclear type. Hemoglobin was 70% by Tallquist. The Von Pirquet skin reaction was negative. No Wassermann test was made, as it was deemed unnecessary in both cases.

Fragility of the red blood corpuscles in both cases was tested by the Senior House Officer, Dr. A. E. Myers, with the assistance of Dr. Karsner, using hypotonic salt solution in the percentages running from .2% to .8% in steps .05%. In the case of G. O. hemolysis began at 45%, was incomplete at .2%. In case of C. O. hemolysis began at .4%, was incomplete at .2%. In the normal control hemolysis began at 45%, was complete at .25%. This would indicate that the resistance of the corpuscles of both patients is slightly increased. This is shown more markedly in the

point of complete hemolysis which occurred at less than .2%, as compared with complete hymolysis which in the normal control occurred at .25%. The value of the experiment lies in the fact that it served to indicate a decreased fragility of the red blood corpuscles in our two patients, whereas in familial jaundice the fragility is said to be increased.

On Oct. 22nd, sixteen days after admission, the general condition showed little change. The jaundice and condition of the mouth were the same, the boundaries of the heart, liver and spleen showed no change. No free abdominal fluid could be detected. The urine contained bile in slightly decreased amount.

He left the hospital on Nov. 4th., four weeks after admission, with condition unchanged except for a decrease in the depth of the jaundice.

During his stay of twenty-nine days in the hospital his evening temperature reached 100 on only seven evenings, and only twice attained the maximum of 101° Farh. During the rest of the time the daily temperature variations were within normal limits. The pulse rate and respirations varied only within normal limits.

While in the hospital both boys on questioning would express a most enthusiastic desire for brandy.

He was last seen on December 9th, approximately two months after coming into the hospital. Since his discharge the urine is said to have become fairly normal in color. The stools have remained hard and white. Recently he has grown more apathetic and drowsy, and if undisturbed sleeps at least half of the day. On examination pulse and respiratory rate were normal. Jaundice and the yellowish discoloration of the sclera were somewhat less marked. The heart area was within normal limits. At the apex a slight systolic murmur faintly transmitted to the anterior axilla was heard, second pulmonic sound much accentuated, action slightly irregular. The abdomen was only moderately distended and no free abdominal fluid was detected. The superficial abdominal veins were fairly prominent, the liver edge was distinctly palpable 7 cm. below the costal margin in the nipple line and 7½ cm. below the xyphoid. The tip of the spleen was felt on a line with the umbilicus and 7½ cm. to the left of it. The condition of buccal and nasal mucosa was practically the same as on discharge.

For the performance of the autopsy on the first case and the subsequent pathological and histological work I am indebted to Dr. Howard T. Karsner of the Pathological department, Harvard Medical School. The autopsy was performed thirty-six hours post-mortem. In brief the anatomical diagnosis is as follows: Acute fibrinous pericarditis with effusion. Chronic interstitial myocarditis, Passive congestion of lungs and conglomerate tuberculosis of left lung. Miliary tuberculosis of right lung. Lobar pneumonia of right lung. Atrophic cirrhosis of liver with regeneration. Miliary tuberculosis of liver. Chronic passive congestion of spleen with follicular hyperplasia and miliary tuberculosis. Passive congestion of intestines. Ascites. Slight arteriosclerosis. Miliary tuberculosis of left peri-bronchial, superior mediastinal, mesenteric, retroperitoneal and subhepatic lymph nodes.

The more detailed report of the gross pathological findings is as follows:

Body. That of a poorly nourished, white male child showing moderate jaundice, no rigor, marked liver mortis and green discoloration over the distended belly. The lower extremities and the forearms show numerous punctate hemorrhages.

Primary Incision. Shows a thin panniculous adiposis and dark red musculature, no bleeding.

Peritoneal Cavity. Contains an unmeasured but large amount of slightly cloudy yellowish-brown, limpid fluid. Peritoneum smooth and glistening throughout. Omentum is very much congested and the organs are all in normal position, spleen reaching about 4 cm. below the costal margin, the liver not being visible.

Thoracic Cavity. Shows a markedly distended pericardium filled with slightly cloudy blood-stained fluid containing flakes of fibrin. Thymus not visible.

Pleural Cavity. Left pleural cavity is smooth and glistening throughout. Right cavity throughout its entirety shows easily broken up fibrinous adhesions and the sac contains a slight excess of slightly cloudy blood-stained limpid fluid containing flakes of fibrin.

Lungs. Left lung is of moderate volume, crepitant throughout except for a very small area in the apex anteriorly and of generally dark red color. Organ cuts with normal resistance and shows a dark red, bleeding, soft moist cut surface. The point of consolidation in the apex anteriorly is found to be near a yellow bulging caseous mass measuring 1 cm. in diameter, fairly well encapsulated, but showing in the immediate neighborhood several small slightly projecting gray tubercles. The pulmonary vessels are normal. Peribronchial lymph nodes are enlarged, adherent to one another uniformly caseous and continuing into the superior mediastinal lymph nodes. Similar involvement is found around the bifurcation of the trachea and the left side of the trachea above the bifurcation. Bronchi show slight congestion, but otherwise normal. The right lung is voluminous and solid, weighs 320 grams in contrast to a weight of 140 grams for the opposite lung. The organ is covered by thin loosely attached, blood-stained fibrinous exudate. The organ is completely consolidated, cuts with normal resistance and above throughout all three lobes dark red, firm, finely granular cut surface which on scraping appears to be dry. Throughout this cut surface, however, a relatively small number of minute, non-projecting, vaguely defined, gray and yellowish-gray masses are found which have the gross appearance of miliary tubercles. They are not closely associated, however, never confluent and in a single section do not number more than 10 to a lobe. The pulmonary vessels of this side are normal, the bronchi are the same as on the other side and the lymph nodes are somewhat enlarged, soft and pink and do not show any caseation.

Pericardium. As noted above contains a great excess of fluid.

Heart. Of about normal size and weighs 120 grams. The epicardium is covered throughout by a blood-stained, loosely adherent, fairly thick fibrinous exudate, thicker over the left ventricle anteriorly than elsewhere and giving rise to a typical shaggy appearance. The hemoglobin staining, however, is extreme. The muscle cuts with normal resistance and shows a retracted, firm, reddish-gray cut surface in which there appears to be an increase of connective tissues. The mitral,

aortic, pulmonic and tricuspid valves show nothing abnormal. The endocardium throughout is thin and transparent and the columnae carnae and papillary muscles normally rotund.

Liver. Weighs 400 grams, measures 16.5 x 9.5 x 3.5 cm. The organ is extremely firm and shows a slightly thickened, smooth capsule with numerous areas in which the sub-capsular veins are considerably distended. The edges are rounded. In several places there are points of nodular bulging immediately under the capsule. These nodules are spherical yellow-white, very well defined and bulge in the cut surface. Their diameters range between one and three millimetres and they have more the appearance of tubercles than of liver substance. Organ cuts with leathery resistance and shows a non-bulging, firm, gray cut surface throughout. Projecting into the cut surface and not clearly visible from the outer surface except in the Spigelian lobe are areas fairly definitely defined, ranging from 2 to 4 mm. in transverse diameter, yellow in color with slightly depressed red centres, generally soft consistence and much more numerous in the right lobe than in the left lobe. In fact, the left lobe is almost a solid mass of this dense leathery, gray, very nearly homogeneous connective tissue. The gall bladder and bile ducts are normal.

In the small intestines at about the middle of the ileum is a small, slightly depressed irregular ulcer generally circular, measuring about 2 mm. in transverse diameter with slightly undermined edges and yellow nodular masses in the elevated margin. A similar ulcer is found at the region of the splenic flexure in the large intestine.

Spleen. Weighs 140 grams, measures 14 x 7.5 x 2.5 cm. It is large, shows a thickened, opaque capsule and is distinctly softened. It cuts with slightly increased resistance and shows a slightly bulging cut surface in which both follicles and trabeculae are distinctly more prominent than normal. In addition there is found in the cut surface a number of slightly projecting well defined, aphorical, yellow nodules which grossly appear to be tubercles.

Adrenals. Show post-mortem congestion.

Kidneys. Weigh together 220 grams. They appear to be slightly enlarged and are extremely soft, capsule strips with ease, leaving a smooth, marked congested outer surface. Organs cut with slightly diminished resistance and show a bulging, soft, dark red, slightly bleeding cut surface. The cortex is thickened and bulging; pyramids sharply defined and purple. Peripelvic fat normal. Ureters and bladder normal.

Lymph-Nodes. Mesenteric, retro-peritoneal and sub-hepatic lymph nodes all show enlargement and are soft. Several of them in transverse section show a bulging cut surface in which are several nodules projecting above the cut surface, fairly well defined, yellow and of the gross character of miliary or small conglomerate tubercles.

Aorta. Shows throughout its length similar fine streaks of thickening and yellowing of the intima to that described in the ascending part.

"On microscopic examination, the right lobe of the liver shows very marked thickening of the capsule of Glisson with marked proliferation of bile ducts and moderate infiltration focally of lymphocytes. The parenchyma shows cloudy swelling, fatty degeneration and central necrosis. Bile pigmentation is found peripherally in many of the lobules. The sections from the left lobe fail to show any remaining parenchymatous tissue; but the central vein, much fibrosed, can be made out and the capsule of Glisson can be distinguished. In the position of the parenchyma, however, there is a marked overgrowth of connective tissue and proliferation of bile ducts. These ducts show low cuboidal epithelial, occasionally show clubbed extremities and in a few cases contain bile, but no transformation into liver cells can be seen. The diagnosis is a cicatricial atrophic cirrhosis, following some acute general destructive lesion. Miliary tuberculosis is also present."

Neither the pathological nor histological findings in this case lend much support to the diagnosis of an alcoholic cirrhosis in the pathologists' opinion. On the other hand, they do not completely discredit this diagnosis and the pathologist can suggest no other more probable cause than alcohol for the changes found in the liver. The histological picture suggests most strongly an acute destructive process such as is seen in acute yellow atrophy or acute atrophy due to phosphorus poisoning. The history, symptomatology, especially the absence of acute gastroenteric symptoms, the comparatively long course all tend to discredit this diagnosis. Furthermore, both children apparently were attacked within a period of three weeks by a disease that in both has presented one at a time symptoms compatible with the diagnosis of an alcoholic cirrhosis, and in both was presumably due to the same cause. It seems most improbable that an acute atrophic process of the idiopathic type or due to poisoning or even to intestinal toxemia could originate in both children at almost the same time and then present in both the same symptomatology and protracted course. The other more common causes of hepatic cirrhosis are fairly conclusively ruled out, I think, as follows:—

1. Congenital lues, by the personal history, negative Wassermann test, the symptomatology, and so far as I now know by the pathological and histological findings.

2. Cardio tubercular cirrhosis, of the type described by Hutinel (quoted by Morse, *ibid*), by the absence of any definite signs or symptoms of cardiac or pericardial origin, by the failure of the Roentgen ray to indicate any pericarditis or mediastinitis, and by the fact that the pericarditis found at autopsy was evidently an acute process of recent origin, and there were no old adhesions, and also no valvular lesions found in the heart.

3. Cirrhosis due to acute infections seems fairly satisfactorily ruled out by the negative history of any acute infection except measles and the fact that the symptoms of liver impairment had been present at least for six months before the attack of measles.

In conclusion from all the evidence now at hand and with full appreciation of the rarity of the condition I am inclined to believe that in both children the initial process was a cirrhosis

of the liver due to abuse of alcohol. I am not sufficiently familiar with the pathological changes in the livers of children dying from acute liver degeneration as a sequel to one of the acute infections to advance the idea as anything more than an hypothesis, but it would seem at least possible that in the one case which has come to autopsy the pathological picture might be accounted for by an initial alcoholic cirrhosis complicated by an acute destructive process as a sequel of the measles infection, and later followed by attempts at regeneration of the liver tissue. The whole picture of course being further complicated by an acute general miliary tuberculosis and terminated by the attack of lobar pneumonia.

For the privilege of reporting both cases I am indebted to Dr. Thomas Morgan Rotch, visiting physician at the Children's Hospital.

XXIII.

The Report of a Case of Multiple Bone Tuberculosis Atypical in its Distribution and X-Ray Appearances.

By Henry J. Fitz Simmons, M.D.

Believing that the report of cases which are unusual and which have been studied by the best methods of the present day may lead to a wider dissemination of knowledge and subsequent more accurate diagnosis I report the following case.

This patient J. R., a boy of sixteen months, came to the Out Patient clinic of The Boston Children's Hospital May 3rd, 1913. The child was born in Boston of healthy parents who are still well and strong and show no signs of organic disease. He was breast fed five months and has always had good care.

Four months before entrance the mother noticed a lump in the child's abdomen which has gradually grown smaller. She brought the child to the clinic for diagnosis and treatment of lumps upon the head.

On entrance the child appeared well developed and well nourished. The skin upon his face was clean and of good color. His hair and nails appeared to be normal. His head was of normal size. Both pupils were equal and reacted to light and distance. The right external auditory meatus contained a foul smelling discharge. The left ear appeared normal. Over the right parietal portion of the skull were three tumor masses, each about ¾ inch in diameter. Two appeared hard and definitely connected with the bone, the other was fluctuant, neither was reddened nor was there any increase in the surface temperature. The posterior cervical and posterior auricular glands were somewhat enlarged but not tender. At the outer canthus of each eye there was a small

Fig. 1.—Showing tumor mass beneath eyes and tumors over the right parietal region of the skull.

fluctuant reddened area about the size of a green pea. Along the descending ramus and angle of the lower jaw on the left side was a nodular thickening which was neither tender nor reddened. The child's mouth was practically negative. No increase in the adenoid tissue was discernible. Teeth were in good condition and the mucous membranes of good color.

The examination of the chest revealed good development with no signs of rickets. No nodulation could be made out along the course of the ribs. The heart percussed within normal limits and its action was regular as to rate and rhythm. The sounds were of good quality and no murmurs were heard. The lungs showed no areas of dullness, no rales nor adventitious sounds.

The abdomen was soft, easily palpated and no masses nor tenderness was found. The liver and spleen percussed within normal limits but the edge of the liver could not be felt.

There was no enlargement of the iliac or inguinal lymph glands.

On the surface of the right thigh are a few small areas that are covered with dark crusts and are surrounded with an area of induration. The right femoral region appeared normal save for these skin lesions and a general thickness about the lower end. This thickness is above and outside the knee joint.

In the region of the upper third of the right tibia on its anterior aspect one could feel an area of thickening about 2 inches long by 1 inch wide.

Beneath the external malleolus and extending towards the cuboid and over the region of the astragalus is a large, tense area of swelling.

The right upper arm appears normal save for some thickness at the lower end of the humerus.

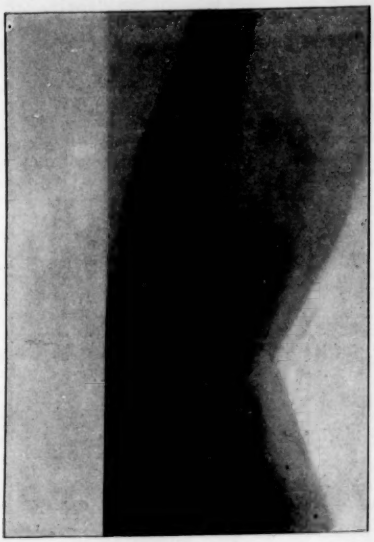

FIG. 3.—Showing lesion in right tibia before operation.

FIG. 6.—Showing lesions about right elbow.

This thickness does not interfere with any movement of the elbow joint. Over the right radial epiphysis is a swelling which is smooth and not attached to the skin, but which is slightly tender. This tumor is apparently connected with the bone beneath. The right hand shows at the end of the fourth metacarpal a pustular lesion covered with a dry scab. The lesion is surrounded with an area of induration ¼ inch in thickness

The left upper leg appeared normal except that two inches below the trochanter is a small indurated dark colored lesion which appeared very superficial. This lesion is about ¼ inch in diameter. Just below the knee and on its outer aspect is a similar skin lesion which appeared to be fluctuant.

The left lower leg presented nothing abnormal except a few scattered skin lesions. Over the first metatarsal of the left foot on the inner side was an area of swelling somewhat reddened but free from fluctuation. This swelling extended from the toes to the ankle joint. The left humeral region presented nothing abnormal. On the extensor surface of the upper third of the left ulnar was a tumor mass which appeared to be connected with the bone but did not involve the skin. This mass was not tender, reddened nor fluctuant.

The left hand presented a fusiform enlargement of the first two phalangeals of the first finger, upon which are dark crusts which were dry and showed no evidence of recent discharge. There was motion in all joints of this hand.

The Wassermann reaction taken at this time was negative. The Luetin test was negative. The Von Pirquet reaction was strongly positive. His blood examination showed leucocytosis 15,600; polyneuclear forms 60%; lymphocytes 40%. There was at this time no myelocytosis present. His urine examination was negative. No Bence-Jones bodies could be recovered from his urine.

Oct. 3, 1913. While the child was under ether a section containing skin and cavity of the two superficial lesions in the left thigh was removed. These were placed in sterile tubes and sent to the pathologist for diagnosis. Both of the cavities contained thick yellowish pus similar to that removed from tubercular cavities. In addition a typical pyogenic membrane was found and easily removed from each. The child made a good recovery and five days after the operation the areas on this leg were discharging moderately and healing in gradually. Twelve days after the operation these lesions had entirely healed without induration or secondary infection.

Oct. 21, 1913. Under ether the small fluctuant mass over the right parietal region was entered but the content of the cavity was too thick to allow aspiration. The needle was withdrawn and sufficient sero-purulent material squeezed out to afford material for culture. A three inch incision was made over the crest of the right tibia immediately below the tibial tubercle. Dissection was carried down without bleeding to the periosteum which was incised over the swelling observed in the bone. A piece of cortex one inch long and one quarter inch wide was removed with a chisel. On the removal of this piece of cortex there escaped some yellow thick purulent material from what appeared to be a well defined abscess cavity. This cavity was lined with a definite membrane which was easily removed. The cavity was wiped out with gauze and the wound closed loosely with interrupted sutures with a small wet wick left protruding between two sutures. The child made a perfectly good recovery from the operation and the wick which had been inserted was removed

after twenty-four hours. The wound at that time was clean and free from induration.

Since the operation the open areas on the left thigh were dressed and were healed solidly in two weeks. The operative wound on the tibia healed by first intention. The child seemed to be doing well except that the swelling which had been noticed on the lower lid and at the outer canthus of each eye increased considerably in size until at this date (Nov. 10th) each was as large as a cherry. The skin over these masses was very much thickened and reddened. Fluctuation was very easily obtained. The three tumor masses over the right parietal region of the skull were still present. The tumor mass which was aspirated is now reddened and showed signs of having become secondarily infected.

Nov. 11, 1913. A small incision about ¼ inch long was made in the dependent portion of each tumor mass located in the cellular tissues under the eyelids. The contents of these abscesses were gently expressed and the opening closed with collodion and cotton. The abscess located over the external malleolus of the right foot was incised, its contents expressed and the wound closed tightly.

Nov. 18, 1913. The right arm was given the usual iodine preparation and under ether an incision was made over the cavity as outlined by the x-ray, two inches below the elbow joint. Considerable induration about the bone at this point was demonstrated. The cortex was then chiselled through and the cavity opened. From this cavity a large amount of yellow caseous material was removed. This cavity was lined with a definite membrane and was about 1 inch in length by one half inch in width. It was swabbed out with iodine and the wound was closed with interrupted sutures without drainage. One of the tumor masses in the right parietal region was opened with the removal of a small amount of yellow purulent material and a small bone sequestrum. The lining wall of the cavity was definite and easily removable. This wound was closed tightly with the exception of a small rubber drain which was left in for twenty-four hours.

Dec. 10th, 1913. The general condition of the child to-day is much worse than it was one month ago, notwithstanding the fact that the child has had the benefit of out-door treatment at the Convalescent Home at Wellesley. The two areas on the parietal region, which were operated upon still show some nodulation. The one that was operated on as a clean wound has completely closed, but the one which was aspirated is still discharging and seems to have become a sinus. The tumors under the lids of both eyes have disappeared but in their place are two ulcerative surfaces ¼ inch in diameter from which exudes purulent material. The area which was incised on the left ulnar is still tender and shows signs of thickness to the same degree that it did previous to the operation. The skin lesions which were found in different parts of the body have now disappeared. The operative wound of the old lesion in the upper portion of the tibia has healed solidly, but there is evidence of bone proliferation beneath. On the lateral aspect of the right foot there is a discharging sinus. This was the situation of the old abscess which was incised. The lower extremity of the right radius particularly on the inner side seems to be somewhat larger than it was two weeks ago and is distinctly tender on palpation. The fusiform swelling of the index finger of the left hand is still present but not discharging.

FIG. 4.—Showing lesion in right tibia, seven months after operation.

A comparison of the x-ray plates taken at an interval of 7 months is interesting in view of the pathological report to follow.

Figure 1 shows lesions on the skull and the tumor mass beneath eyes previous to the operation.

Figure 3 shows the lesion in the right tibia before operation. Figure 4 shows the same lesion four months after the operation.

Figure 6 shows the lesions about the right elbow. The lesion in the ulnar has since been operated upon.

The child on December 10th had a positive Von Pirquet skin reaction. The leucocyte count was 7,800 of which 58% were polyneuclear forms, 42% were lymphocytes and the blood showed no myelocytes. The urine examination was negative. No Bence-Jones bodies were obtained.

The bacteriologists have been unable to grow the material sent to them from the numerous operations, on the usual laboratory culture material.

The pathologist reports as follows: The specimen from the ulnar shows typical tubercles, necrotic central areas surrounded by tubercles and necrotic bone trabeculæ; there is here as in the tibia evidence of osteal proliferation. The specimen from the tibia consists of a fragment of cortical bone having adherent to its inner surface a mass of greyish tissue 4 mil. in diameter. A section through the fragment of bone and adherent mass shows the latter to contain morthologically typical tubercles, solitary and multiple surrounding areas of necrosis. There is an erosion of the cortical bone in the region adjacent to the tubercular tissue. The periosteal surface of the bone shows distinct osteal

proliferation with the formation of new trabeculae. The specimen from the skull marked septic shows necrotic debris only, the specimen from the skull marked clean shows necrotic debris with peripherally poorly formed tubercles.

I wish to acknowledge my indebtedness to Dr. Halsey B. Loder of the department of Surgical pathology of the Harvard Medical School, for the pathological work done on this case.

XXIV.

THE SIGNIFICANCE OF THE VON PIRQUET REACTION IN SURGICAL TUBERCULOSIS IN CHILDREN.*

BY L. BRUCE ROBERTSON, M.D.

Of the various tuberculin reactions, that described by Von Pirquet in 1907, has, in the hands of the majority of observers, proved to be the safest and least disturbing. Of the other reactions, namely the subcutaneous, the ophthalmic and the per-cutaneous or Moro reaction, suffice it to say that the sometimes unpleasant sequelae of the first, the local disturbance of the second, and the variability of the third are enough to recommend the simplicity and ease of the cutaneous test. The explanation[1] of the local reaction in the Von Pirquet test is still theoretical, but it is believed to be due to a hypersensitivity of the infected organism displayed on reinfection, accounted for by the presence of antibodies or bacteriolysins which have been produced as a result of the primary infection, the mechanism of the reaction consisting in the breaking up of the introduced virus and the liberation of a toxic substance in the skin, with its inflammatory effect at the point of inoculation. Occasionally when the test is negative at the first trial, a second attempt a short time later will result in a positive reaction. It is doubtful if an individual can be sensitized by the tuberculin absorbed at the first inoculation to such an extent that he will react, solely on that account, to the second inoculation.[2] The explanation may lie in the natural progress of the disease or in the action of the tuberculin on some latent focus irritating it to such a degree that antibodies are formed which give rise to the reaction at the second inoculation.

The method of application of the Von Pirquet test pursued at the Children's Hospital, Boston, is as follows: The skin over the anterior surface of the forearm is cleansed with 70% alcohol and allowed to dry. Two very small drops of the undiluted old tuberculin ("O. T.") are placed upon the prepared area about four inches apart, a circular control scarification extending into but not through the skin is now made midway between the drops by means of the ordinary watchmaker's screwdriver, and similar scarifications are made through the drops of tuberculin. The arm is held either by patient or nurse until dry, a matter of a few minutes.

The reaction due to trauma is seen in practically every case and is of no importance. It consists of a wheal about each scarification followed by a zone of hyperemia, which disappears within a few hours. The true reaction consists essentially of a hyperemic indurated zone about the scarification and appears as a rule within the first eighteen hours, becoming most pronounced during the second 24 hours and fading gradually in the next three to six days, leaving a desquamating, sometimes pigmented, area. In the very intense reactions, vesiculations may occasionally occur, the induration is more pronounced and the color a deep reddish purple. The periphery of such an area may be jagged with reddish streaks along the course of the superficial lymphatics leading from the area of reaction. One of this nature subsides slowly, and it may be two or three weeks before the desquamation and pigmentation have disappeared.

The object of the present investigation was to determine the reliability of the Von Pirquet reaction in surgical tuberculosis, particularly that of bones and joints. The statements made apply rather to the more severe types of bone and joint infection as the less severe types are treated in the out-patient department without being admitted to the wards.

The material consists of some 350 cases on which the Von Pirquet reaction was tried, collected from the records in the last 4 years. The children were all under 12 years of age.

CASES ADMITTED TO HOSPITAL WITH DIAGNOSIS OF TUBERCULOUS DISEASE OF THE SPINE

Number of cases, 71. Ages from 14 months to 10 years. Number of positive Von Pirquet reactions, 65. Cases in which the reaction was negative, 6.

CASE 1. G. A. Age, 18 months. Duration of symptoms, 3 months. Patient had history of pneumonia following whooping cough 6 months before, and signs of pulmonary involvement were still present. The lower lumbar vertebrae were affected and a large lumbar abscess present was opened. Child showed a severe grade of toxemia and died in hospital after developing an empyema.

CASE 2. E. W., 7 years of age. Duration of symptoms, 3 months. A second Von Pirquet test 5 days after the first one resulted in a positive reaction.

CASE 3. E. S., 9 years of age. Admitted with a question of tuberculous disease of the lumbar vertebrae. The x-rays were negative and the whole condition entirely cleared up in 10 days, probably a sprain of spine.

* From the Orthopedic Department, Children's Hospital, Boston

Case 4. E. F. Age, 3½ years. Admitted with question of tuberculous disease of spine and knee. This was probably not a tuberculous condition as the condition had entirely cleared up in 6 months.

Case 5. D. St. H. Age, 8½ years. T. B. spine and knee, with discharging sinus; duration, 5 years. Von Pirquet negative.

Case 6. P. N. Age, 3½ years. Tuberculous disease of spine. Double psoas abscess. Duration of symptoms according to history, 1 month. Von Pirquet negative.

One case with positive reaction later proved to be an acute exacerbation of a chronic cervical adenitis.

CASES ADMITTED TO THE HOSPITAL WITH DIAGNOSIS OF TUBERCULOUS HIP DISEASE.

Number of cases, 74, ages from 10 months to 11 2-3 years. Number of positive reactions, 67. Cases in which the reaction was negative, 7.

Case 1. M. M. Age, 2 years. Von Pirquet tried 6 months later and positive reaction obtained.

Case 2. G. H. Age, 2½ years. Von Pirquet test negative in May, 1910. The patient had had hip symptoms for 8 months, chronic bronchitis since measles two years before, and general condition was poor. Several months later she developed pulmonary tuberculosis. A second Von Pirquet test was tried (Dec. 4, 1913), and found positive.

Case 3. W. C. Age, 7 years. Clinical history of 1 year duration. Von Pirquet reaction negative. The case was under observation only two weeks and has not reported to the out-patient department since, so that diagnosis is still unproven. X-ray showed an anatomically incipient process in hip.

Case 4. A. C. Age, 4 years. Tuberculosis of hip with abscess formation. Duration of symptoms, 10 months. Nothing to account for negative reaction. Attempt made to follow up case, but child had been taken to New Hampshire.

Case 5. E. G. Age, 2 years. Admitted with question of T. B. hip. Duration of symptoms, 1 month. Leucocytes, 22,000. Four days after admission abscess in right iliac glands was opened and drained. Patient was discharged from hospital 1 month later with abscess almost healed and hip symptoms having subsided to a considerable degree. Diagnosis suppurative iliac adenitis.

Case 6. J. C. Age, 2 years. Admitted with question of tuberculosis of hip. Duration of symptoms, 3 weeks. The x-ray showed a destructive process in the great trochanter. Seven months later the child returned to the out-patient department wearing no apparatus and condition apparently cured.

Case 7. J. K., 2½ years of age. Diagnosis, tuberculosis of hip with pathological dislocation. The patient showed a very severe grade of toxemia, and pathological examination of tissue obtained at operation on the hip showed the presence of tuberculosis. Three successive Von Pirquet tests were negative.

CASES ADMITTED TO HOSPITAL WITH DIAGNOSIS OF TUBERCULOUS DISEASE OF THE KNEE.

Number of cases, 21. Ages, 2-8 years. Number of positive reactions, 20. The only negative reaction was in a boy 6 years of age. Duration of symptoms, 2 years. Von Pirquet test was tried on four different occasions and found negative.

CASES ADMITTED TO THE HOSPITAL WITH DIAGNOSIS OF TUBERCULOUS DISEASE OF THE ANKLE.

Number of cases, 14. Age, 2-5 years. Number of positive reactions, 14.

CASES ADMITTED TO THE HOSPITAL WITH DIAGNOSIS OF BONE OR JOINT TUBERCULOSIS ELSEWHERE THAN MENTIONED ABOVE.

Number of cases, 7. Number of positive Von Pirquet reactions, 7. Shoulder, 1; radius, 1; wrist, 1; dactylitis, 2; osteomyelitis of tibia, 1 (proven by pathological examination of bone obtained at operation); os calcis, 1. Totalling those cases in which a definite diagnosis of *bone or joint tuberculosis* could be made, we find 3.2 per cent. of negative reactions in 182 cases.

Of other tuberculous conditions for which patients were admitted there were 20 cases, in all of which the Von Pirquet reaction was positive. This list comprises: Tuberculous cervical adenitis, 14 cases; tuberculous peritonitis, 2 cases; tuberculous kidney, 1 case; tuberculous abscess of thigh, 1 (diagnosis proven by pathological examination); tuberculosis of hernial sac, 1 case; multiple tuberculous lesions, 1 case.

Of cases admitted with a diagnosis other than that of tuberculosis there were: Rickets, 20 cases. The Von Pirquet reaction was negative in 18 cases. Positive reactions.

Case 1. Patient aged 3½ years with knock knees. Showed no clinical evidence of tuberculosis.

Case 2. Patient aged 3 years with knock knees. Showed healed cervical adenitis with scar in neck.

Infantile paralysis, 18 cases. Von Pirquet reaction negative in 16 cases. Positive reactions.

Case 1. Patient aged 11½ years, has slight enlargement of cervical lymph nodes. Patient's father died of pulmonary tuberculosis.

Case 2. Patient, aged 5¾ years, showed palpable lymph nodes in anterior triangles of neck.

Osteomyelitis, 21 cases. Von Pirquet reaction negative in 16 cases. Positive reactions.

CASE 1. Age, 10 years. No clinical evidence of tuberculosis.

CASE 2. Age, 8 years. No clinical evidence of tuberculosis, but a family history of tuberculosis was present.

CASE 3. Age, 3¼ years. Von Pirquet reaction was negative in the first trial and positive 1 year later when patient was found to have developed cervical adenitis.

CASE 4. Age, 3¾ years. Patient shows old tuberculous glands of neck.

CASE 5. Age, 10 years. Patient had enlarged palpable cervical glands. The father died of pulmonary tuberculosis.

Congenital deformities, 28 cases. Von Pirquet reaction negative in 26 cases. Positive cases.

CASE 1. Age, 5 years. Patient showed no clinical evidence of tuberculosis.

CASE 2. Age, 2½ years. Patient had tuberculous glands of the neck.

Arthritis (non-tuberculous), 5 cases. The Von Pirquet reaction was negative in 4 cases.

In the single positive case, a child aged 6½ years, with multiple arthritis following otitis media, a chronic otitis media was still present which was not definitely non-tuberculous.

Synovitis of hip, 8 cases; of knee, 1 case. Number of negative reactions, 8.

In the 1 positive case, a child 3 years of age, there was no clinical evidence of tuberculosis, but the father and one sister have pulmonary tuberculosis and the mother died of it.

Epiphysitis of femur, 4 cases. Von Pirquet reaction negative in one case. Of the 3 cases in which positive reactions were obtained none showed any definite evidence of tuberculosis, although one showed enlarged tonsils and another had a family history of tuberculosis.

Flattened head of femur,[3] 2 cases, both of which gave positive Von Pirquet reactions. In neither case was there other clinical evidence of tuberculosis. One case gave a family history of tuberculosis.

Of other conditions, including acute suppurative lymphadenitis, pyogenic abscesses, sarcoma, traumatic bow-leg, renal calculus, hematoma of the abdominal wall, rupture of the liver, septic ankle, progressive muscular atrophy empyema, syphilitic periostitis, cirrhosis of liver, infectious diarrhea, scoliosis, cyst of neck, cyst of femur, ovarian cyst, Volkmann's ischaemic contracture, burns of body, hernia, hydrocele, appendicitis and pericolic adhesions, there were 43 cases, of which 36 showed negative Von Pirquet reactions. Of the cases in which a positive reaction was obtained, one had enlarged submerged tonsils, another had enlarged anterior cervical glands, while the remaining five showed no clinical evidence nor family history of tuberculosis.

To sum up, in all cases having clinical evidence of surgical tuberculosis, either in bone or soft tissues, 2.9% showed negative Von Pirquet reactions. In those cases not showing definite clinical evidence of tuberculosis, although some showed enlarged anterior cervical glands and others gave a family history of tuberculosis, 14% showed positive cutaneous reactions.

In the apparently non-tuberculous cases, the reaction is more frequently negative in the younger children, as seen from the following:

0-4 years, 48 cases. Positive reactions in 10%.

4-8 years, 61 cases. Positive reactions in 14.5%.

8-12 years, 40 cases. Positive reactions in 17.5%.

The reaction may be regarded as specific, and the fact that it is positive in a moderately small percentage of clinically non-tuberculous children does not outweigh its value as a diagnostic test. From the above figures it must be concluded that the Von Pirquet reaction is fairly reliable in children under 12 years of age, but that it has less significance where the patient shows enlargement of the anterior cervical lymph nodes or gives a family history of tuberculosis. The frequency of positive reactions in cases giving a family history of tuberculosis is well shown by Brown[4] in his statistics from the Babies' Hospital, New York. The tuberculous lesion may not necessarily be active, but up to the present time there has been no recognizable difference between the local reactions occurring in active and those in presumably latent cases.[5] It is stated that the reaction may be absent where severe toxemia is present,[6] and this fact would seem to be borne out by the two negative reactions occurring in two of the above-mentioned cases, one of tuberculous hip and one of tuberculous spine.

There is a much greater proportion of positive reactions in apparently non-tuberculous cases than of negative reactions in those clinically tuberculous.

The Von Pirquet reaction is said to be absent in measles during the incubation period and for several days after the rash has appeared. Evidence to this effect has been given by Von Pirquet and later by Moltschanoff.[7] The latter gives 100% of negative reactions in measles and 85% negative reactions in scarlet fever.

There has been an attempt made recently to differentiate between active and latent tuberculosis by noting the leucocyte count both before and after the Von Pirquet reaction, and Chiaravalloti[8] has shown in a series of cases of active pulmonary tuberculosis that there is a

definite increase in the total and polynuclear count after the cutaneous test. After investigating some 20 cases consisting of bone and joint tuberculosis and tuberculous peritonitis in the Children's Hospital, with this point in view, we found such a lack of uniformity in results that it was only justifiable to conclude that this test of the so-called "general reaction" to the Von Pirquet test is, at least in its present state, not applicable to cases of surgical tuberculosis

Book Reviews.

State Board Questions and Answers. By R. Max Goepp, M.D. Third edition. Thoroughly revised. Philadelphia and London: W. B. Saunders Company. 1913.

The second edition of this work was reviewed in the issue of the Journal for July 27, 1911 (Vol. clxv, p. 141). In this third edition considerable new material has been added, particularly with reference to serology, chemotherapy, syphilis, tropical disease, and cardiac physiology. Considerable old and superfluous material has also been eliminated, particularly in the field of materia medica; so that the total increase in size of the book is only two pages. Like its predecessors, it should be useful to teachers "as a repository of typical questions, a guide of instruction," and an evidence of the present demands of American examining boards upon candidates for registration in medicine.

Ulcer of the Stomach. By Charles Bolton, M.D., D.Sc. (Lond.), F.R.C.P. (Lond.). New York: Longmans, Green and Company. London: Edward Arnold. 1913.

The author has collected much clinical and pathological data concerning gastric ulcer. He tells us, in his preface, that he purposely omits any discussion of duodenal ulcer. The book, which is nearly 400 pages long, impresses one as of more value as a book of reference than a monograph on the subject of gastric ulcer. In an attempt to make the work complete a considerable amount of irrelevant material is introduced, so that the continunity is lost and with it interest lags. Most of the material is stereotype and very little is either new or personal. The book abounds with references and no statements are made that are not backed up by citation of authorities. In this regard, at least, the book is admirable.

Diseases of the Heart. By James Mackenzie, M.D., F.R.C.P. Third edition. London: Oxford University Press. 1913.

This excellent work is so well known that the third edition requires no extended review. A comparison with the last edition published in 1910 shows what definite progress has been made in the precise diagnosis of diseases of the heart, more particularly in the field in which Mackenzie has been a pioneer, namely, cardiac irregularity. The book throughout is clear, and admirably arranged. Epecially lucid and convincing are the hundred pages devoted to the various forms of cardiac irregularity. An appendix with ninety-two case reports is of great assistance in the illustration of the points that the author desires to make. The book is well printed on good paper and concludes with an admirable index.

Mind and Health. With an Examination of Some Systems of Divine Healing. By Edward E. Weaver Ph.D., sometime Fellow in Clark University, with an introduction by G. Stanley Hall, PhD., LL.D., president of Clark University. New York: The Macmillan Company. 1913.

The author aims in this book of 500 pages, including a bibliography and index, to present in popular form, the present status of the psychotherapeutic movement. An introductory historical statement is followed by a discussion of the theories of mind and the principles of psychotherapy, as propounded by both the older and more recent writers on the subject. The bias of the author is clearly shown by the fact that a very large portion of the book is concerned with the various religious systems of healing, all of which are discussed with an open mind and with liberal quotation from original sources. The work lacks interest to physicians because of the over-emphasis placed on the religious aspects of the matter. Whatever the future may bring forth, for the present it is desirable to study facts without prejudice, and without emotional appeal, and this the author fails to accomplish. In spite of this defect and also of unnecessary verbosity, the book is written with sincerity and should certainly serve as a guide to the more popular religious aspects of psychotherapy. It does not adequately cover the more searching psychological studies of recent years, upon which the whole subject must ultimately rest.

THE BOSTON
Medical and Surgical Journal

THURSDAY, APRIL 2, 1914.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States. $6.56 per year for all foreign countries belonging to the Postal Union.*

Papers for publication, and all other communications for the Editorial Department, should be sent to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston. All orders for reprints must be sent in writing to the Editor on or before the day of publication.

The Journal will furnish 100 reprints free, if requested in writing.

All letters containing business communications, or referring to the publication, subscription or advertising department of the Journal, should be addressed to the undersigned.

Remittances should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

THE CHILDREN'S HOSPITAL.

THIS issue of the JOURNAL is published as a *Festschrift* in honor of the forty-fifth anniversary of the founding of the Children's Hospital. The completion of this period of its life coincides with the opening and occupation of its new group of hospital buildings near the Harvard Medical School. The good fortune of this transition from an old to a modern and more favorable environment should prove not only an increased opportunity for service, but a fresh stimulus to continuance of activity and progress in medical study.

The history of the Children's Hospital has been associated with names of distinction in medicine and in surgery. Its development was intimately a part of the life-work of the late Dr. Thomas Morgan Rotch, who contributed the second article in this series, and whose untimely death on the eve of its publication is doubly lamentable in that he could not see the completion of his cherished projects. The reputation of the Children's Hospital, however, has not been made in pediatrics alone. Surgically, distinction for the hospital has been won by the department of orthopedics. The history of this surgical progress is amply reviewed in the fifth article of this series.

The remaining papers, by other members of the hospital staff, present a number of special details in the work of the Children's Hospital, and give an idea of the range and variety of its activities. Like all good hospitals, it has always been devoted not solely to the relief of the sick, but to the pursuit of medical research and the furtherance of medical education. In its new and more intimate local association with the Harvard Medical School, the opportunities and possibilities of this aspect of its work should be still further increased, and in every respect the hospital should share in the impetus given to each constituent part of a great medical centre. Its well-wishers look forward from the completion of this epoch in its history to another of even brighter success and more distinguished achievement.

ADVANCE IN HOSPITAL ADMINISTRATION.

IT is fitting on this occasion of the opening of the new buildings of the Children's Hospital, to call attention to progress in administration which indicates a marked change in attitude toward the teaching of medicine, and which will place the facilities of this hospital more completely at the service of the best in medical education than has hitherto been done. It is a long road from the conditions indicated in the first report, covering the time from the opening on July 19, to the end of the year, December 28, 1869, to those brought out in the last available report, for the year 1912. The original house in Rutland Street was opened for thirty patients. The hospital on Longwood Avenue will accommodate one hundred and fifty, and is capable of almost indefinite expansion. There is in addition a convalescent home. The budget for the first six months, including property, was a little over twenty-five thousand dollars; that for 1912 was over a million and a half, exclusive of the convalescent home.

During this time the contributions to medical knowledge, as well as the relief of suffering, have been commensurate with the opportunities given, and as the hospital enters its new quarters, the managers, with the hearty support and upon the recommendation of the staff, give new evidence of their interest in medical progress.

Realizing that the closer the union between a hospital and a good teaching institution, the better the interests of the patient are served, the

board of managers, several years ago, entered into an agreement with the Corporation of Harvard College, by the terms of which vacancies in staff positions should be filled by nominations from that corporation, dependent upon confirmation by the board of managers of the hospital. This agreement contemplated only members of the visiting staff as usually understood. Recently, however, the board of managers has taken a further step, which is unique, so far as we know. At a special meeting held on February 23, 1914, acting upon the suggestion of the staff and of the executive committee, it voted to create the positions of visiting pathologist, visiting bacteriologist, visiting chemist, visiting pharmacologist, and visiting physiologist, and in accordance with the agreement, the Corporation of Harvard College was requested to make nominations to fill them. This has been done and these visiting positions are to be filled by members of the laboratory staff of the Harvard Medical School, as follows: Assistant Prof. Howard T. Karsner to be Visiting Pathologist, Prof. H. C. Ernst to be Visiting Bacteriologist, Prof. Otto Folin to be Visiting Chemist, Prof. Reid Hunt to be Visiting Pharmacologist, Prof. W. B. Cannon to be Visiting Physiologist.

The purpose of the managers of the hospital in creating these positions is that these five men shall make regular visits to the wards and shall supervise the work of the hospital in their special fields. They are to be regular members of the visiting staff and are to have full privileges in the wards with due regard to the welfare of the patients and the necessary routine work of the hospital. They will not, of course, be troubled with the need of voting on such routine matters as the appointment of house officers, but in other ways the intention is that they shall have the full privileges of staff membership.

The difference between these and existing conditions is the difference between what is indicated by the term "consultant" and the term "visiting," and that this is great any one familiar with hospital management will not hesitate to acknowledge. The action is notable as recognizing the importance of the closest possible relationship between hospital and laboratory. Such a step would not have been possible when the hospital was opened, for there were no laboratories. It is commonly not thought of now, but the slightest reflection and knowledge of medical history will show how far reaching and important it may prove to be.

THE ROBERT BENT BRIGHAM HOSPITAL.

On Sunday, March 15, the buildings of the new Robert Bent Brigham Hospital, on Parker Hill, Roxbury, were informally opened for inspection by a company of over 2000 invited guests. The completion of these buildings and the beginning of their active service mark the addition of another modern and fully equipped hospital to the large and rapidly growing group of medical institutions in Boston centering about the Harvard Medical School.

The Robert Bent Brigham Hospital will be devoted to the care of chronic diseases, surgical and medical. Its staff is composed of well-known and able older and younger physicians and surgeons of Boston. Architecturally the buildings, of brick and limestone, form a fine structure in the modified Greek style, and from their commanding location not only are well seen but enjoy an almost ideally hygienic situation. The details of their equipment are of the most elaborate and approved modern type. The hospital begins its work under the most favoring conditions, and should contribute worthily to the service of the community and to its medical distinction.

MEDICAL NOTES.

Honors for Dr. Gorgas.—On Monday of last week, March 23, Dr. William C. Gorgas, Surgeon-General of the United States Army, was entertained at dinner by the medical profession of London, in recognition of his work in the sanitation of Panama. Among those present were Sir Rickman Godlee, president of the Royal College of Surgeons; Sir Francis H. Champneys, president of the Royal College of Medicine; Sir Thomas Barlow, president of the Royal College of Physicians; Sir Francis Ferrier, president of the Medical Society; Sir Havelock Charles, president of the Society of Tropical Medicine and Hygiene; Sir William Osler, Regius professor of medicine at Oxford; Sir Clifford Allbutt, Regius professor of medicine at Cambridge; Surgeon-General Arthur W. May, medical director general, Royal Navy; Sir William Lancelot Gubbins, director general, Army Medical Service.

On March 24, Dr. Gorgas received the honorary degree of Sc.D. at Oxford.

SIZE OF FRENCH FAMILIES.—In connection with the declining French birth-rate, a comparative study has recently been made of the number of children in French families. Of 11,000,000 families, 2,000,000 were found to be without children, 3,000,000 had one child each, 2,500,000 had two, and 1,500,000 three children each. There were four children in 1,000,000 families; five in 500,000; six or over in the remainder. There were 34 families with 17 children each and 45 with 18 each.

TYPHOID IN THE MERCHANT MARINE.—Dr. Rupert Blue, Surgeon-General of the United States Public Health Service, has recently issued an open letter to managers and masters of lake and river vessels in this country, calling their attention to the high prevalence of typhoid infection among American seamen aboard such craft. During the year ended June 30, 1913, there were admitted to the United States marine hospitals 392 cases of typhoid fever among members of the merchant marine, besides many others treated in public hospitals and at home. During this period there were no cases in the United States Navy. Dr. Blue therefore urges wider adoption of antityphoid vaccination.

BUBONIC PLAGUE IN HAVANA.—Three new cases of bubonic plague were reported at Havana on March 26. One of the patients has already died.

HOSPITAL BEQUESTS.—The will of the late Mrs. James N. Gamble, which was filed for probate on March 25, at Cincinnati, Ohio, contains a bequest to Christ Hospital in that city.

BOSTON AND NEW ENGLAND.

SCARLET FEVER AT YALE.—Report from New Haven, Conn., states that on March 20 there were eight cases of scarlet fever among students at Yale College. Every step has been taken to prevent further spread of the infection.

REGISTRATION OF DENTISTS.—Of 84 candidates who took the examinations on March 4, 5, and 6 before the Massachusetts State Board of Registration in Dentistry, only 28 were passed.

MASSACHUSETTS HOMEOPATHIC HOSPITAL.—The recently published forty-fourth annual report of the Massachusetts Homeopathic Hospital records the work of that institution for the calendar year 1913. During this period 6,508 patients were treated in the main hospital, 12,411 in the out-patient department, 1,040 in the maternity department, 811 in the children's ward, and 455 in the contagious department. From the training-school 27 nurses were graduated. There is urgent need of a new ward for children, and of $100,000 for the erection of a maternity building.

MONSON STATE HOSPITAL.—The recently published report of the Monson State Hospital at Palmer, Mass., records the work of that institution for the year ended Nov. 30, 1913. The total number of patients treated during this period was 1163, of whom 604 were men and 559 women. There were 65 deaths. Considerable progress has been made on the construction of a new building for 130 male patients.

NEW ENGLAND BAPTIST HOSPITAL.—The recently published twentieth annual report of the New England Baptist Hospital records the work of that institution for the calendar year 1913. During this period 722 patients were cared for, of whom 50 were obstetric cases. A total of 383 surgical operations was performed. From the training school a class of eight nurses graduated. The hospital has a legacy to provide and equip a new and much larger building. At present the question of selecting a site is still under consideration.

HOSPITAL BEQUESTS.—The will of the late Caroline Crowell, of Haverhill, Mass., disposing of property whose value is estimated at $56,700, gives one-fourth of the residuary estate to the Hale Hospital of that city.

The will of the late Charles R. Lawrence, of Brookline, Mass., which was recently filed in the Norfolk probate court at Dedham, Mass., establishes a trust fund, of which, upon the death of the principal beneficiaries, one-fourth each is to be given to the Children's Hospital and the Massachusetts General Hospital, Boston. The Massachusetts General Hospital is also made residuary legatee.

The will of the late Sarah E. Pratt, which was recently filed in the Suffolk probate court, contains bequests of $1000 each to the Perkins Institution for the Blind and the Massachusetts Charitable Eye and Ear Infirmary.

The will of the late Joseph C. Storey, of South Boston, who died on March 15, contains

bequests of $10,000 to the Massachusetts General Hospital and $5,000 to the Perkins Institution for the Blind. The residue of the estate constitutes a trust fund which, upon the death of the testator's widow, is to revert in equal shares to these two institutions.

The will of the late Martha B. Webb, of Brookline, Mass., which was allowed in the Norfolk probate court on March 25 at Dedham, Mass., contains a residuary bequest to the Beverly (Mass.) Hospital.

Cases of Infectious Diseases reported to the Boston Board of Health for the week ending March 24, 1914: Diphtheria, 49, of which 2 were non-residents; scarlatina, 130, of which 24 were non-residents; typhoid fever, 6, of which 1 was non-resident; measles, 43, of which 1 was non-resident; smallpox, 1; tuberculosis, 44, of which 4 were non-residents.

The death-rate of the reported deaths for the week was 18.75.

NEW YORK.

American Society for the Control of Cancer.—The first of a series of meetings under the auspices of the American Society for the Control of Cancer was held at the Women's Cosmopolitan Club on March 24. The speakers were Frederick L. Hoffman, LL.D., who has collected many statistics on the subject of cancer, and Prof. James Ewing of Cornell University Medical College. The latter took issue with Mr. Hoffman on statements made by him that cancer is essentially a disease of civilization and that radium is of no value in its treatment. Dr. Ewing expressed the opinion that many local malignant growths could be cured by radium, if treated sufficiently early. The limit of the penetrating power of its rays, he said, appears to be one and one-half or two inches, and the correct dosage of this agent has not yet been definitely determined.

Work of Montefiore Home.—The twenty-ninth annual report of the Montefiore Home and Hospital for Chronic Invalids shows that during the past year 1,083 inmates were cared for, of whom 472 were still under treatment. All the patients except 43 were treated free. The new buildings in the Bronx, to which the home has lately been removed, were erected at a cost of $1,965,000, and, with its country sanatorium for tuberculosis at Bedford Hills, the institution is now able to care for 700 persons suffering from chronic and incurable disease.

Report of the Loomis Sanatorium.—The recently published seventeenth annual report of the Loomis Sanatorium for the Treatment of Tuberculosis records the work of that institution for the year ended Oct. 31, 1913. During this period 372 patients were admitted. In treatment, special attention was devoted to tuberculin, artificial pneumothorax, and the employment of graduated exercise for the production of controlled auto-inoculation. An urgent appeal is made for funds to assist in reducing the sanatorium's debt of $147,000.

Legalization of Chiropractic.—Report from Albany states that on March 25 the State Senate passed bills extending to chiropractic and naturopathy the same legal recognition now given to osteopathy.

9. ABT, I. A. *Unusual Type of Acid Intoxication in Infants.*
10. FOX, H. *Experience with Neosalvarsan at the Harlem Hospital.*
11. PEMBERTON, R. *The Metabolism, Prevention and Successful Treatment of Rheumatoid Arthritis. Second Contribution.*

1. Barker, after consideration of the different types of joint disease described both in ancient and in modern times, proposes a classification under the following main headings: 1. The true gouty arthropathies. 2. The arthropathies of severe nervous disease. 3. The (primary) hypertrophic osteoarthropathies. 4. The secondary chronic arthropathies, following various infections, and those following small foci of infection in various parts of the body. 5. The so-called (primary) chronic progressive polyarthritis.

2. Spiller, in discussing discouraging statistics in operations on brain tumor, writes particularly of the unfavorable effect upon the operative results of enlargement of the brain from tumor, distortion of the brain, especially from tumor in the posterior cranial fossa, and acute swelling of the brain,—all conditions which usually may be avoided by sufficiently early operation and proper technic.

3. MacCallum reports experiments which seem to prove that in animals injected with diphtheria toxin the heart is not materially weakened. This finding lends support to the theory that death in diphtheria may be due to vasomotor rather than cardiac failure.

4. Rudolf reviews the conflicting statements of the effect of hemorrhage in typhoid fever upon the course of the disease, some authors failing to recognize any favorable influence, while others support the evidence of Graves and of Trousseau, that improvement may follow. He publishes twelve charts of typical cases in which hemorrhage occurred (in one by venesection), in all of which the loss of blood was followed by a fall in temperature and improvement in the general condition without unfavorable effect on the pulse.

5. Halsted reports briefly upon experimental work upon excision of parts of the thyroid gland under aseptic precautions which failed to result in the hyperplasia of the remaining thyroid tissue which occurred in former experiments without asepsis. The explanation remains obscure.

6. James and Hart write to show how misleading an index of the condition of the circulation is the count of the radial pulse in auricular fibrillation. Of greater value is the simultaneous counting of the apex beat and of the radial pulse for recording which the authors have devised a method of indication on a chart. Of more interest is a method which they describe of determining the average systolic blood-pressure in these cases where the beats are of unequal force. The administration of digitalis caused a rise in blood-pressure thus estimated. [F. W. P.]

8. Simon, C. E., and Wood, M. A. *The Inhibitory Action of Certain Analine Dyes upon Bacterial Development.*
9. *Stern, H. *Typhlo-albuminuria.*
10. Pemberton, R. *The Metabolism, Prevention, and Successful Treatment of Rheumatoid Arthritis: Second Contribution.*

1. Deaver has collected 69 proved cases of mammary tuberculosis from the literature and adds 5 original cases. These he analyzes and discusses in detail both from the clinical and the pathological point of view. All but one were operated by one method or another, without operative mortality. The disease is regarded as essentially a surgical one, although tuberculin treatment is recommended as of possible value when used in conjunction with operation.

2. Camac writes to emphasize the importance of recognition and treatment of oral sepsis as a not infrequent source of arthritis, endocarditis, and of other septic processes in remote parts of the body, even though the manifestations at the original focus may be slight. Radiographs, a number of which accompany the article, are the chief means by which such processes are recognized.

3. Withington describes the occasional occurrence of hemiplegias in pneumonia. These are found generally in young and rather vigorous people and often end in recovery. Since the few cases that have come to autopsy have failed to show organic lesions in the brain, the cause is unknown.

5. Greenwald reports chemical examinations of the blood serum of patients with paralysis agitans to determine the content of acid-soluble phosphorus, a constituent notably increased in parathyroidectomized dogs. His failure to find that this is increased in paralysis agitans he reports as evidence against the theory that this disease is due to parathyroid insufficiency.

6. Cohen reports cases with joint symptoms in which the features seemed to warrant the conclusion that they were angioneural in origin. He discusses the clinical characteristics of these cases and refers to the literature.

7. Beer reports a case in which following attacks of renal colic shreds of pearly white membrane of the structure of epidermis were found in the urine. These are believed to have been thrown off from a surface of leukoplakia in the pelvis of the kidney.

9. Stern maintains that albuminuria without other evidence of kidney disease may be due to a communication of the lymphatics of the cecum with the urinary tract. [F. W. P.]

Berliner Klinische Wochenschrift.

No. 5. February 2, 1914.

1. *Bumm, E. *Further Experiences in the Therapy of Carcinoma by Irradiations.*
2. Warnekros. *On the Technic of Roentgen Treatment of Carcinoma.*
3. Lazarus, P. *The Present Status and New Aims of Radium-Mesothorium Therapy (First paper).*
4. *Pinkuss, A. *Further Work on the Mesothorium Treatment of Cancer.*

6. Grabs, E. *Experiences with Digifolin.*
7. *Kleinschmidt, P. *Clinical Experiences with Isopral as a Rectal Anesthetic.*
8. Buchholtz, F. *A New Successful Method of Treatment of Acne.*

1. The author, in a very enthusiastic report, presents 108 cases treated with radium or mesothorium. Only 40 of these cases were operable, and though some of them had been followed for only six months, only 15 of the 108 showed recurrences at the time of the communication. Of 12 cases of carcinoma of the cervix, nine were seemingly cured (to date), 2 had recurrences and 1 was not markedly affected.

The destructive effect of the rays is found to extend about 2½ cm, below the surface—not as deep as 3½ or 4 cm., as others have claimed. The radioactive substances do not have a selective action on carcinoma, as has been stated, but the young and active tumor cells are more rapidly and completely destroyed than are the connective tissue and supportive cells.

4. This is a short critical review of the whole subject of mesothorium therapy. Pinkuss suggests that carcinoma of the stomach can be treated by making a fistula through which the substance can be brought into close contact with the growth; he does not favor the method of passing it into the stomach on a sound or bougie passed down from above. He doubts the value of intravenous injections of thorium-x, as has elsewhere been suggested and tried. The best results of all treatment with radio-active substances are dependent on more exact knowledge of the proper dosage, time of application, and filtration; and careful working-out of these factors is of supreme importance.

7. The author has used isopral in 43 cases, giving 0.1 gm. (per rectum) per kilo body weight, one hour before operation. In five cases no further anesthetic was necessary; in all the rest it was. In 4 cases the effect of the drug was very slight, and in 4 others there was no effect at all. Seven cases, after waking up, were for several hours in a highly restless and excitable condition—at times out of their heads and almost maniacal.

The toxic effect in some cases was extremely marked, showing itself chiefly in the poor pulse, altered breathing and general appearance. Kleinschmidt concludes that although in some cases its action is almost ideal, its use is not to be generally recommended. [R. H. M.]

Correspondence.

ANTIVACCINATION AND THE LEGISLATURE.

Boston, March 28, 1914.

Mr. Editor: To the great surprise of many intelligent people the legislative committee on public health, Drs. Clarke, Bigelow and Hart dissenting, has reported favorably a bill permitting unvaccinated children to enter the public schools of the Commonwealth upon the written request of any parent or guardian who may not believe in vaccination. At present a physician's certificate is necessary for such admission. The bill was introduced and advocated by the antivaccination agitators.

Should the bill become law, much harm in the future will be the inevitable result. The number of unvaccinated persons in the community, already too large, would be greatly increased, thereby flooding the state with material ripe for infection upon slight exposure. Its enactment would be a decided step backward in legislation towards the days when smallpox was always in our midst, not infrequently springing up in epidemics, maiming and destroying large numbers of persons needlessly and inexcusably. It would be difficult to imagine any action of the legislature that would be more ill-advised, or more cruel to the helpless portion of the community and especially to the children of the poor, the ignorant and the careless, who are unable to protect themselves properly.

As the direct result of wise legislation, Massachusetts has been practically free from the dreadful scourge of smallpox for forty years. The present generation knows little or nothing of it. Only

those who remember the last severe epidemic in Boston in 1872-3, when nearly 4000 were attacked and over 1000 died, can begin to realize the terror, the distress and the demoralization of the daily activities of the community in consequence of its presence. The outside world shunned us. Business fell off to a marked extent and the attention of the people was focused chiefly upon the state of the epidemic. Can it be possible that another object lesson of this sort is necessary to enable us to appreciate the absence of this pestilence?

This disease is preventable, but not curable. The chief factor in its prevention is vaccination. Its value has been incontestably demonstrated in all civilized countries for more than a hundred years. Time is wasted in arguments on this question in well-informed circles. Vaccination, properly done and attended to, is one of the safest surgical operations known to the medical profession. For nearly ten years Massachusetts has prepared vaccine virus for distribution to its citizens free of expense. About half a million doses have been sent out and used with no known ill results. No purer, or more reliable virus has ever been made anywhere.

No one claims that accidents never occur after vaccination, as they occasionally do after the most trivial injuries. Within eight years the writer has seen one death from the prick of a pin and one arm amputated for the scratch of a needle, yet pins and needles have not been given up, nor has any legislation been sought to prohibit their use, as yet. The risks of our every-day life far exceed those from vaccination, while the benefits derived from the latter surpass our comprehension. The accidents are preventable. They are so rare that they are a negligible factor in the question.

Sensible people everywhere are so firmly convinced of the protective power of vaccination that they will continue to avail themselves of its benefits regardless of any legislation, past, present or future. Adults can protect themselves, or take the consequences. The helpless children of ignorant or thoughtless parents, however, deserve the protection of the state. That is the chief object of the present vaccination laws. It cannot be possible that in these days of unprecedented efforts to lesson the mortality of the young, we are ready to abandon one of the most efficient measures for accomplishing that object known to modern civilization. In some of the former epidemics smallpox destroyed half of the children under five years of age, to say nothing of the blindness and other mutilations in those who recovered. It is desirable to return deliberately to conditions approaching in any degree those of former times?

A word as to the evidence of the parties in hearing. One party consists chiefly of a few well-meaning, but terribly mistaken and irresponsible persons, whose vision is not achromatic, *i.e.* who do not see clearly, who accept cheap newspaper clippings, neighborhood gossip, etc., as evidence. They never refer to official records, as there are none favoring their peculiar ideas. They endeavor to prove their case with a lot of stuff that would not be accepted in any court in the land. Their judgment is so warped that they can see only one side of the question and will not accept any evidence not agreeing with their claims. As the lawyers say, they are not competent witnesses.

The other party to this discussion comprises the medical profession all over the civilized world, whose opinion is based upon the experience of more than a century, the sanitarians, health officers and all others having to do with health problems, together with a very large proportion of the intelligent public everywhere. The alacrity with which the general public resorts to vaccination in times of danger, shows their confidence in the measure. The evidence in its favor is so overwhelming that one is lost in amazement that its value can be questioned in these enlightened days. Is it reasonable to suppose for a moment that the great mass of intelligent people the world over is wrong on this matter and that the few persistent agitators are right? If the wonderful benefit of vaccination has not been proven, then nothing in this world is susceptible of proof.

If the members of the legislature believe that the reliable, the official history of vaccination and its effects is a lie, if they believe that the medical profession is composed of hypocrites and mountebanks preying upon the public for pelf, if they believe that under the pretence of "personal liberty," the helpless children of the commonwealth should not be protected, if they believe that the antivaccinationists are better and more reliable judges of the points at issue, than are the physicians, then they will vote for House Bill 1018, which is but an entering wedge to the repeal of all laws relating to vaccination.

On the other hand, if they believe with the medical profession and the vast majority of intelligent people everywhere that vaccination is a public benefit and hence that the citizens of the commonwealth should be protected from smallpox, as they have been for forty years, they will oppose the bill in question, thereby following the wise procedure of many former legislatures.

GEORGE W. GAY, M.D.
For The Massachusetts Medical Society.

Miscellany.

CHANGES IN THE MEDICAL CORPS, U. S. NAVY, FOR THE TWO WEEKS ENDING MAR. 21, 1914.

March 19, P. A. Surgeon W. H. Short from Receiving Ship at Mare Island, Cal., to the *Cleveland*.

March 17, Surgeon A. R. Alfred, from Naval Proving Ground, Indian Head, Md., to Training Station, San Francisco, Cal.

P. A. Surgeon H. L. Dollard, to Naval Proving Ground, Indian Head, Maryland.

P. A. Surgeon I. W. Robbins, Commissioned from March 28, 1913.

Asst. Surgeon C. I. Wood, M.R.C., Commissioned from February 24, 1914.

Asst. Surgeon J. M. Quinn, M.R.C., Commissioned from February 24, 1914.

March 18, P. A. Surgeon I. S. K. Reeves, detached from *Tacoma* to *North Carolina*.

Asst. Surgeon C. P. Lynch, detached from Naval Medical School, Washington, D. C., March 28, 1914, to *Tacoma*.

March 19, Surgeon C. D. Langhorne, detached from Marine Barracks, Washington, D. C., to the *Vermont*.

March 20, P. A. Surgeon M. C Baker, from *Pittsburg* to *Chattanooga*.

APPOINTMENTS.

DR. T. MITCHELL PRUDDEN, emeritus professor of pathology in Columbia University, has been appointed by Governor Glynn a member of the New York State Public Health Council.

DR. RUDOLPH E. DIEDLING of Saugerties has been appointed by the governor of New York a commissioner of prisons.

RECENT DEATHS.

DR. DANIEL SIMMONS, who died recently at Brooklyn, N. Y., was born in 1844. He served throughout the Civil War in the ranks of the Eighty-third New York Volunteers. Subsequently he studied medicine, and in 1872 received the degree of M.D. from the New York Homeopathic Medical College. He was a member of the American Institute of Homeopathy and of the Kings County Medical Society. He is survived by his widow and by one daughter.

Original Articles.

GONORRHEAL METASTATIC ARTHRITIS.

By H. W. E. Walther, M.D., New Orleans,

Clinical Assistant in Genito-Urinary and Venereal Diseases in the Tulane University School of Medicine; Assisting Visiting Genito-Urinary Surgeon to the Charity Hospital.

Since the year 1781,when Salle and Swediaur first made mention of a condition which they described as "an inflammatory articular affection dependent upon gonorrhea," that systemic complication of gonorrheal blennorrhagia now commonly known as gonorrheal rheumatism or more correctly as gonorrheal metastatic arthritis has, as Keyes states, claimed a greater share of the attention of the profession than its frequency warrants,—a claim which is due to its activity and its severity. That its importance is being more generally recognized is demonstrated by the fact that within the past few years much new thought has been added to the already voluminous literature on this interesting subject, and although all agree on the importance of early recognizing this condition clinically, still no two writers agree on the method of treatment. For this reason it has occurred to the writer that a compilation of the ideas expressed by the recent contributors on this affection together with a summary of their methods of treatment would be of material value.

Hahn of Breslau, who has made an exhaustive study of this disease, states that of the numerous metastases of gonorrhea which he has met with in his vast experience, gonorrheal rheumatism deserves first place. It has been reported from conservative workers that between two and three per cent. of all our patients suffering with Neisserian urethritis become afflicted with this disease. The malady is more common in men than in women. It has been found that the condition may be due to constitutional invasion and localization in the synovial membranes of joints, tendons, and bursae by the gonococcus alone, sometimes apparently to mixed infection, with pyogenic bacteria in addition. It occurs frequently after the passage of a sound into the urethra. Many cases have also been reported in vulvovaginitis of little girls and in gonorrheal ophthalmia of babies. Krissel states that women seem to be almost immune to this complication, which is supposed to be due to the fact that the vagina and not the urethra is the usual seat of gonorrhea in the female. This, however, is only a supposition. We find the initial infection at least as often in the female urethra as in the vagina. He believes moreover that the cause of this apparent immunity is to be found in the difference of the structures of the female urogenital tract and, secondly, to the lesser chance of traumatic injury to the urethra and vagina in the course of treatment of a gonorrhea. In the light of our present knowledge of the etiology of gonorrheal metastasis, it requires either local retention with a subsequent trauma of some sort or an abrasion of the protecting epithelium in order to allow the escape of the bacteria or their toxins into the blood-vessels or the lymphatics. Such a trauma may be a mechanical one, but a sexual excitement or a congestion from any source may serve the same purpose. Epithelial lesions may be produced by instrumentation, but the invasion of the deep urethra or the vesical neck and the trigone by the gonorrheal process leading to more or less congestion and bleeding is sufficient to expose smaller blood-vessels and offer an escape of the bacteria and their toxins. Neither endourethral instrumentation nor the invasion of the posterior urethra and the trigone usually occurs in the earliest stage of the disease and, therefore gonorrheal metastatic arthritis is rarely observed in this stage. It is rather the exception than the rule for our patients to develop symptoms of this malady in the acute stages of a gonorrheal infection, although I have seen it develop in the third and fourth weeks following the initial symptoms. It is rarely seen at an earlier period. In chronic cases it oft times appears before the prodromal symptoms make their appearance.

Two cases, as illustrations of early onset, which are still fresh in my memory, occurred some years ago while the writer was a resident interne in the Marine Hospital at New Orleans. The first instance was in the case of a stoker in the Navy who developed metastatic arthritic symptoms on the thirteenth day following his initial urethral infection with the gonococcus, and the second instance occurred in a marine whose arthritic symptoms developed exactly twenty-one days after his first clap. In both instances the patients denied all previous venereal infection and I had no reason to doubt the truth of their statements.

As to the number of joints which become involved, statistics show that in about 30 per cent. of the cases one joint only is involved and that in the remaining 70 per cent. the lesions are polyarticular. Regarding the distribution of gonorrheal metastatic arthritis, Lovett quotes 755 cases from the collective figures of Northup, Finger and Benecke and states that in their cases the joints were affected in the following order of frequency:

Knee	258
Ankle	125
Wrist	76
Elbow	53
Small joints of hand	50
Small joints of foot	46
Shoulder	44
Hip	42

Heel and toes	21
Temporomaxillary	16
Other articulations	24

These figures, I believe, compare favorably with those of all other workers who have taken the pains to tabulate their findings. All agree that the knee is the joint most commonly involved and sometimes we find it the only articulation affected. Large, swollen and intensely painful ankle and wrist joints are also common pictures in this disorder. The other joints are involved much in the same proportion as given in the figures above.

I desire here to report a case which to me was very interesting because of the fact that the articulation involved is one not commonly invaded by the gonococcus. The patient was a white male, single, 25 years old and a tailor by occupation. He gave a history of having contracted gonorrhea six weeks previously, had taken no treatment for the urethritis and he came to me, not for the urethral condition, but for severe pains "back of his right hip" as he described it. He still had a profuse urethral discharge in which I had no trouble demonstrating Gram-negative diplococci, there was swelling and severe pain on pressure over right hip localized to the area directly over right sacro-iliac joint and his suffering was so intense that it was with effort that the patient walked or even stood erect. Temperature 101 F. Joint was aspirated and 10 cc. of serous fluid withdrawn in which gonococci were demonstrated by centrifugal methods. Prostate and seminal vesicles were normal. The treatment consisted in absolute rest in bed, immobilization of affected hip with adhesive plaster strips, energetic local treatment for urethral condition and Bier's active hyperemia to affected joint. In two weeks time the urethral discharge had greatly diminished, the pains in the hip had disappeared and within three and a half weeks the patient was back at his usual occupation. Two years have now elapsed and there has been no return of the trouble.

The types of this affection that we usually see come under the following five headings:

1. Arthralgia without definite lesions in the joint.
2. Acute serous synovitis with much peri-articular swelling.
3. Acute fibrinous or plastic synovitis with slight effusion.
4. Chronic serous or purulent synovitis.
5. Involvement of peri-articular structures, such as bursae and tendon sheaths.

As to the management of cases of gonorrheal metastatic arthritis much has been written within the last few years. Practically everything known in therapeutics has been tried in the hope of finding some amenable remedy for this troublesome complication of gonorrhea but unfortunately, up to the present time at least, we have no absolutely dependable fixed method of treatment which we might conscientiously follow. Among the methods which have been vaunted from time to time might be mentioned: the employment of the galvanic and the faradic electric currents, the Röntgen rays, radium, the actual cautery, active and passive hyperemia according to the methods of Bier, wet hot and cold packs, blistering, tincture of iodine, ichthyol, and similar preparations locally applied, vaccines, serums and the bacterial derivatives. Of the surgical treatments we might mention aspiration alone, aspiration with injection of Murphy's two per cent. formalin in glycerin, arthrotomy and the Fuller operation of seminal vesiculotomy. These are but a few of the many methods; the list could be carried along *ad infinitum*.

Some years ago Kreissl was asked by a colleague how he treated his cases of gonorrheal rheumatism and his reply was, "By treating the gonorrheal focus." I am sure that today we all agree with him that this is the only logical procedure to follow for if the joint disease is due primarily to a gonorrheal urethritis, the inflammatory arthritis will subside promptly if the source of infection is eliminated. All of our injections, irrigations, dilatations and topical applications will fail to relieve our patients if the retention foci are not removed, be they in the prostate, the seminal vesicles, in Cowper's glands, in the follicles or in the crypts.

Cumston has recently laid great stress on the prophylactic measures which he has employed with success in the treatment of cases of gonorrheal rheumatism. He advises the internal administration of salol in five to ten grain doses, four times daily after meals and at bed-time. He cites a case of a physician who had gonorrhea twice and on both occasions there developed a severe tenosynovitis of the tendons of both feet. With this patient's third infection he was placed on ten grains of salol four times daily and the writer ends his report by stating that the patient rapidly recovered from the urethritis under local treatment and no symptoms of gonorrheal rheumatism appeared.

It seems still to be a disputed question as to whether the affected parts should be completely immobilized or not, and while many who have written on this subject recommend that the joints be absolutely immobilized over the entire period of the inflammation, others, among them Hume, are inclined to be more conservative and advise that the joint affected be kept in splints no longer than twelve hours on a stretch for fear that permanent ankylosis of the part may result therefrom. During the interval, in which joint is removed from the splints, passive movements might be practiced so as to retain its function as much as possible.

Pain is frequently a factor to be reckoned with in these conditions and whereas in some instances it will be mild and transitory, at other times it is of such a nature as to require the administration of morphine, codeine, veronal or the salicylates to relieve same. In gonorrheal tenosynovitis, which Cumston states is the mildest form of gonorrheal rheumatism, he advises rest of the parts affected and in intense pain he states that blood-letting works like a charm. Although I have not employed this latter method myself, it certainly is worthy of a trial.

The massage of the prostate and seminal vesicles seems to play an important part in the relief so frequently reported in some cases of this malady. Kreissl advises that massage of the prostate and seminal vesicles should be performed daily of from one-half to one minute duration, and states that this treatment should be kept up until no more septic material appears in the washings for at least two weeks, and even then it should be discontinued by gradually increasing the intervals between massaging.

Locally to the joints, lead and opium lotion, ice caps, hot or cold wet packs, saturated solution of magnesium sulphate, ichthyol fifty per cent., and the actual cautery have, I believe, given most satisfactory results. Holland instructs his patients to drink one-half gallon of water daily and to eat light, easily digested food, without much meat. He gives his patients an early morning bath, after which they are put to bed until noon; in the afternoons freedom is allowed if no pains are felt. Bier's obstructive hyperemia by means of the elastic bandage. should be employed early in the treatment of gonorrheal metastatic arthritis. The sooner after the onset of the articular pains the elastic bandage is applied, the better will be the results obtained. Bier stated that in cases in which this treatment is started within the first few hours after the pain sets in, the improvement is often so rapid and striking that the correctness of the diagnosis may be questioned. In three cases I have had the opportunity to verify these statements. I have seen three patients within a day after the initial symptoms of the rheumatism had set in. All three cases had been treated by me for chronic posterior urethritis of gonorrheal origin. I immediately applied the elastic bandage, also elevated the limbs in the interval of treatment in order to reduce the edema. Two treatments daily were given of ten hours each. In all three cases I found a marked diminution of pain in the parts affected, and also increased mobility. The treatment was continued for twenty hours daily until the fever had subsided and then the time of treatments daily were reduced. Bier's active hyperemia (steaming or baking the joint) has also been used with good results, in selected cases, but as a rule its results have not been as encouraging as those obtained by the passive hyperemia with the elastic bandage.

As far as can be ascertained, the actual value of the serums, vaccines and the bacterial derivatives in the treatment of gonorrheal arthritis has not been finally determined. It is commendable to note here that the fourth congress of the German Urological Association, which met in Berlin in the fall of last year, had an interesting symposium on serotherapy and vaccine therapy in its relation to urology, in which such men as von Wassermann, Schneider and Asch discussed this question. It is to be hoped that in the near future more will be known as to the actual value of these agents in genitourinary surgery. Hartwell, who reported a series of cases of gonorrheal arthritis treated by the vaccines, and who was one of the first in this country to try them in this condition, sums up his article by stating that: "From observations on 51 cases it would seem that gonococcus vaccines are a valuable therapeutic agent in gonorrheal arthritis in all stages of the inflammation except where ankylosis has occurred. They do not however, seem to be able to prevent extension to fresh joints in early cases, and certainly do not produce enough lasting immunity to prevent recurrence of arthritis. Autogenous vaccines seem to be more efficient than stock, thus corresponding to the known specificity of biological substances."

W. G. Young has reported 28 cases of gonorrheal rheumatism treated with the vaccines with these results: cases cured 20; improved 5; not improved 3. The doses he employed varied from 5 million to 50 million bacteria, and I think his results interesting because he states that practically no other treatment was employed in this series excepting the vaccines. J. S. Read, and, more recently, Holland have reported excellent results by using the mixed (polyvalent) gonococcus vaccine. Holland uses an initial injection of 400 million, followed in two days with 500 million; four days later he gives 900 million and this dose is repeated every four days until the desired results are obtained. Broeman has emphasized the importance of treating every case of gonorrheal rheumatism immediately with either the antigonococcus serum, gonococcus vaccine or the newer bacterial derivatives whether they are stock or autogenous products. The combined bacterins (Van Cott) seems to be more useful than the single strain cultures. The initial dose he places at between 10 and 20 million, running up the dose every second, third or fourth day, until about 50 million are being given every second or third day. Usually within a week or ten days improvement may be expected, but from four to six weeks elapse before all symptoms have subsided. The antigonococcic serum is administered in the same manner.

Nothing has yet been found that does a particle of good when given internally to our cases of joint complication following gonorrheal infection, so with this statement we can con-

scientiously pass over the internal treatment for something more promising.

The newer surgical procedures at our command, which have been employed in combating this Frankenstein of urology, have undoubtedly done much toward curing the severer forms of the disease. Of the numerous operations advocated by their enthusiastic originators, I will content myself by making mention of but four, namely, (1) aspiration of the joint alone; (2) aspiration of joint plus the injection into same of some antiseptic or disinfectant; (3) making incision into joint, irrigating and draining same according to the method of Schuller; and (4) Fuller's operation of seminal vesiculotomy. Taking them up separately we might say that it is reasonable to believe that some cases have apparently been cured by simply aspirating the accumulated fluid from the affected joint; sometimes a single aspiration will suffice, while in other cases the procedure must be repeated at intervals as needed. The aspiration of gonorrheal joints with the injection of an antiseptic or disinfectant solution has been popularized by Murphy in this country and by Hildebrand and Roux in Europe. Murphy uses a two per cent. dilution of liquor formaldehydi in glycerin, and of this solution he injects 5 to 20 cc. depending upon the quantity of fluid aspirated and the size of the joint. With this method he has reported excellent results and many other reports just as promising have come from other writers who have given this method a fair trial. The technique of Hildebrand and Roux differs little from that recommended by Murphy except that they inject tinctura iodidi (3i to 3iii) into joint instead of liquor formaldehydi.

When either or both of the above treatments fail, the joint should either be freely opened, cleansed, packed and drained, or double drainage should be instituted with daily through and through irrigations of 1-5,000 bichloride of mercury solution.

Fuller of New York has recently given us a new method for curing our cases of gonorrheal arthritis by his operation of seminal vesiculotomy. Up to the present time Fuller has performed this operation 251 times, 122 of which were for gonorrheal metastatic arthritis, without a single fatality. In his last report the author shows that most of the cases, both acute and chronic, were of very severe grade and it was primarily for the relief of the rheumatic symptoms that seminal vesiculotomy was done. He believes that the rheumatism is the clinical symptom of seminal vesiculitis which usually, by incapacitating the individual, brings him to the hospital; and in his experience at the City Hospital, when those suffering from rheumatism see the rapid cures resulting with little post-operative discomfort in those who have been subjected to seminal vesiculotomy, there is such a scramble for operation that no time has to be wasted in persuasion. In a personal communication to the writer, Fuller states that it is not logical, in his opinion, to employ any local treatment in this disease, for he claims that such treatment is decidedly faulty in that the individual is not freed of the primary focus which causes the toxemia of which the joint is only one of the evidences.

Up to the present time however, the Fuller operation has found few enthusiasts, the reason, I believe, being that most conservative surgeons look upon this operation as rather a severe ordeal to subject patients to, and most of us would prefer to try every other means at our disposal before having them undergo this operation. To do this operation undoubtedly requires some skill and experience. The technique cannot be properly acquired from the literature. To have seen this operation performed several times by a competent surgeon is, in the opinion of our leading urologists, the only manner in which it can be thoroughly mastered.

FURTHER OBSERVATIONS OF SEASONAL AND METEOROLOGIC INFLUENCE UPON TUBERCULAR PATIENTS.

BY N. B. BURNS, M.D., NO. READING, MASS.

Assistant Superintendent, North Reading State Sanatorium.

Through the year 1913 we continued our study of the correlation between certain phenomena manifested by tubercular patients and meteorologico-seasonal change. This is in accordance with the interesting results learned from a similar investigation carried on during 1912 and published one year ago.[1]

It should be worth while to collect facts and data pertaining to such clinical observations as seem casually to have some connection with weather change and to arrange them along side meteorologico-seasonal change. This is in accurrence. For this purpose corresponding indices on the charts represent the respective variations; and it can be noted almost at first sight the amount of coincidence or correlation occurring from day to day and month to month.

In this way a graphic arrangement by means of correlative indices gives a ready and impressive picture of the influence which the weather might have upon any group of tubercular patients in this locality.

"We live in the laboratory of the earth's atmosphere" says Prof. Ward of Harvard University.[2] This is particularly true of the sanatorium patient who, although sheltered from the extremes of weather, is so intimately associated with his natural out-door environment that he can hardly escape the influence of its

changes. Hence we should except the likelihood of some reaction by the tuberculate arising from weather and seasonal variations.

Our bodies try to adjust themselves to the changing conditions of the medium in which we live. A healthy individual although naturally better equipped with compensatory powers for adapting himself to his varying atmospheric environment has the means of seeking close shelter for the larger part of twenty-four hours, and especially from so-called undesirable weather; therefore he is perhaps not so readily subject to meteorological influence except if he be an individual who "incubates" to such an extent that exposure to any weather change effects him profoundly.

However, it should be said that among those patients who take all that the treatment offers, spending a maximum amount of time in the open air, that such a thing as a "cold" is very rare. While this patient is afflicted with a serious constitutional disease, he is nevertheless able to withstand the rigors of riotous atmosphere better than his well brother who must be inside the greater part of each day.

Last year our study was confined to the patients' weight changes by months, and at the same time to the effect of supplementary diet as a remedial measure in combating such of these changes as were of an unfavorable nature. In 1913 we investigated the same matter. Plates similar to those of 1912 are herewith presented.

Perhaps the best exhibit is the Gaining Weight Chart. The heavier index in the larger compartment represents the total number of pounds gained since admission by the male patients who have shown an improvement; at the foot of the chart may be seen two subjoined indices, the heavier of which represents the number of individuals in the male class gaining. The lighter indices above and below refer to female patients in the same manner. The number of patients involved in the make-up of this chart ranged between one hundred and ten and one hundred and thirty-five. The daily average number of patients for the year 1913 at the sanatorium was 178.56.

On this chart it is interesting to note:

(1.) The high points reached in the colder months and the sharp decline in the spring months, especially from the latter part of March to the middle of July when the low point is reached.

(2.) The women gained weight rapidly in January and February, also in September and October.

(3.) The large gain made by both wards during two weeks in October when the weather was so unpleasant that walks and exercise were much restricted and rest treatment in maximum amount was naturally in order.

(4.) Both indices leave off at the end of 1913 at a higher level than at the beginning of the year. Possibly this may be accounted for by the better cooperation on the part of patients, since the formation of the *"Sanatorium-Hospital Class"* system, whereby a greater number of patients are taking the treatment faithfully and therefore deriving greater benefit. Especially among the female patients did the sanatorium class distinction appear most popular, which may be one reason for their gross gain index running up so rapidly in the fall and early winter.

(5.) Since the total census declined slightly during the latter part of the year and since the number of patients discharged per month varied only in a small way, these two factors are practically negligible, in considering the index movements.

The trend of the indices of this chart correspond with those of a similar chart of 1912, confirming our ideas that the spring of the year constitutes a quite unfavorable season for the consumptive.

It is a matter of clinical observation that anorexia is then a common symptom among a clinic of tuberculates, which probably accounts for a considerable loss of weight.

There may appear an attendent mental phase characterized by depression, irritability of temper, unreasonableness and sometimes delusions. Thus, food which was most palatable and satisfactory to the patient during the winter months, not only loses its attractiveness, but is foresworn by the patient as "bad," "not cooked right," or "I can't eat that stuff." There seems to be a vicious circle, for with all this mental restlessness, comes a greater activity and a genuine and dangerous "spring fever."

Plate No. 2 is a discount chart which applies to the gaining weight chart. The idea is to have all the charts check up accurately to the census of the Institution, and also to explain for such part of the index movements as are clearly removed from probable seasonal influence. Thus "Patients not Weighed" and "Patients with Stationary Weight" account for the patients not enumerated on plates one and three.

Two indices which are not printed herewith deal with the census increase and the amount of meat consumption by months. The former increased from one hundred and seventy-two on March first to one hundred and eighty-two by the middle of July and then dropped to one hundred and eighty in October, which figure was maintained for the remainder of the year. Thus in those months of greatest decline in weight gained the census was increasing and was clearly a minimizing rather than exaggerating factor in determining the true intensity of seasonal variation in the spring months.

Dealing with meat consumption, the index falls in the warm months and rises sharply in the fall and winter, attesting to the genuine quality of the appetites of that season.

The "Weight Gained by Discharged Pa-

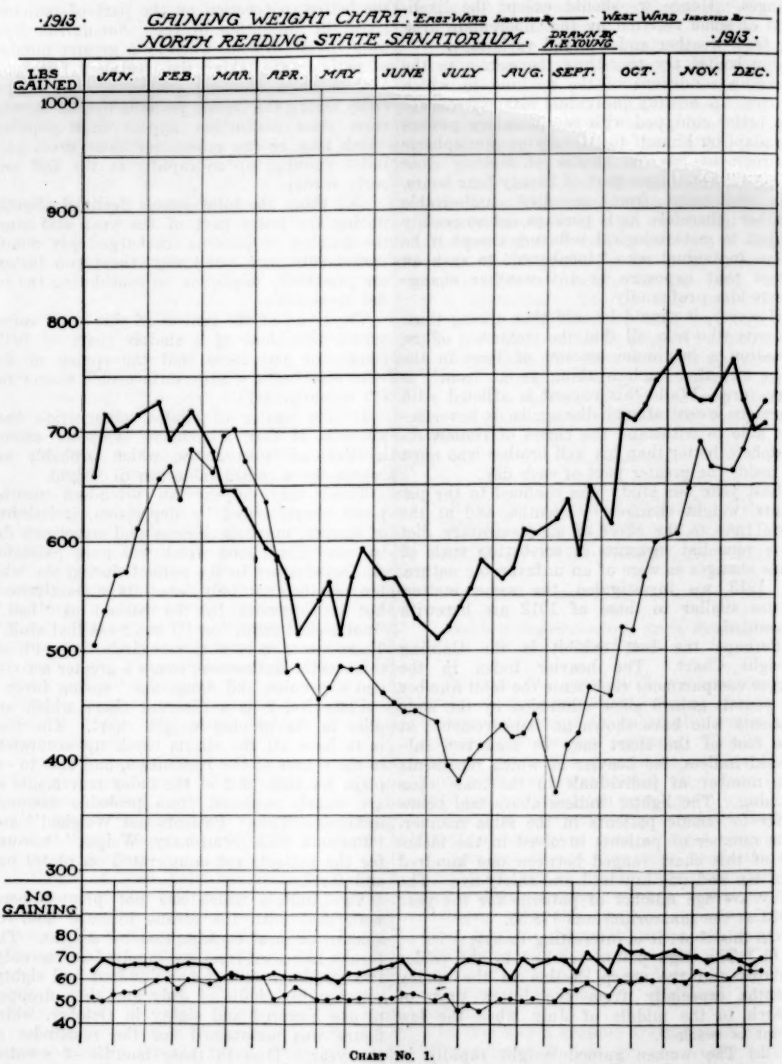

CHART NO. 1.

tients'' provides figures per week which should discount certain fluctuations shown on Plate No. 1. For instance, during the week of April seventeenth, female patients credited with ninety pounds of gained weight were discharged from the institution. A loss of one hundred pounds is shown on Plate No. 1 for that week. After allowing for weight discharged, a net loss is seen, which seems characteristic of that particular season of the year.

On the other hand from October sixteenth to the thirtieth patients' gains of seventy pounds were discharged in spite of which the main female index gained about eighty-five pounds, making a gain of one hundred and fifty-five pounds; thus there is a sharp contrast between the tendency in the spring months to

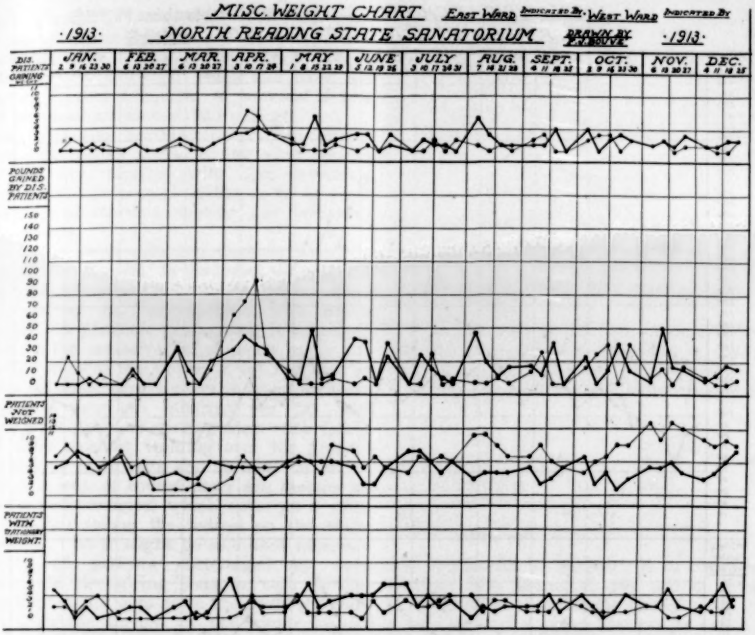

Chart No. 2.

cease taking on weight and that of the fall and early winter to gain weight and to improve in general condition.

Plate No. 3 gives four indices interpreted similarly to those of Plate No. 1 except they relate to emaciation rather than to gain in weight. This chart deals with those patients who were under admitted weight and registers quantitatively perhaps better than any other index could the activity of progressive disease in patients suffering with pulmonary tuberculosis. Three things are noticeable:

(1.) The minimum amount of weight loss occurs in the colder months; (2.) The maximum loss occurs in the warmer months; (3.) The rapid increase in amount of emaciation which appears in the spring months.

The final decline in weight of terminal cases is not shown on this chart because the weakness of such patients precludes their weighing for perhaps a long time before the end. Yet the last weight, taken some time before, must be reckoned in each week's account.

Some reason for the rebound in the lost weight indices in August and September is afforded by the fact that deaths in July outnumber all other months. The losses of patients dying are erased from the loss account and the index falls.

The factor causing the greater drop in these indices especially in the fall and winter months is constituted in the sort of patient who was below admitted weight in spring and summer but has managed to regain his weight lost and even to cross the line demarcating the gains from the losses, which change removes his records from Plate No. 3 to Plate No. 1. This change appearing in so many individual cases is confirmed in the aggregate by the direction of the indices on Plates Nos. 1 and 3.

In addition to the weight changes by months we began in 1913 an index chart picturing at various levels from the top down the records of daily barometer and wet and dry thermometer. These make three daily index curves and form "the weather department." The observations are taken on the premises and are usually about the same as reported by the United States Weather Bureau at Boston, Mass.

On lower cross lines are shown indices representing each day respectively; the total number of patients having streaked sputum and hemorrhages; the total number of bed patients; the total number having vesperal fever; and the total number having increased cough and chest soreness. By following the upright down one can see for any particular day the kind of weather which obtained and then the quanti-

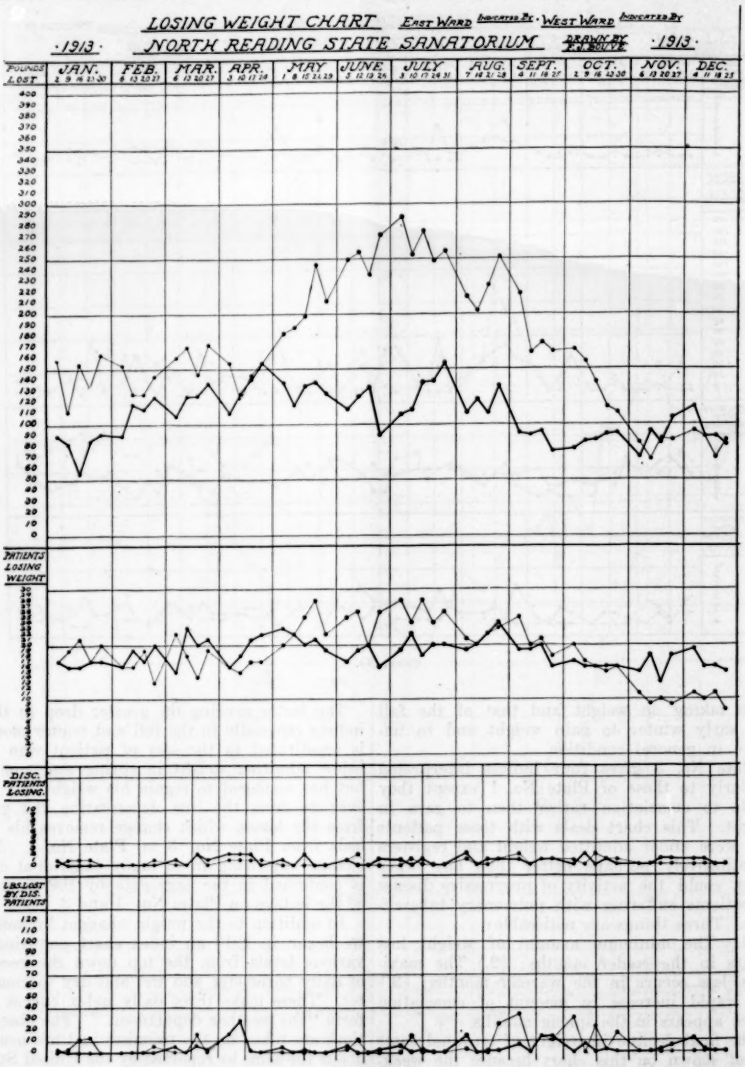

CHART NO. 3.

tative clinical reaction upon a group of approximately one hundred and eighty-five patients of which seventy-five per cent. are in the advanced stage. Whether there is a relation of cause and effect and if so how intense is the question at hand.

Reviewing the four charts which make up this series for the year the following observations can be made:

(1.) Barometer change seems to have very little affect upon the symptomatology. In a few instances hemorrhages have occurred following a fall in the barometer but in insufficient number of instances to justify constant relation. It is probably a matter of coincidence only in so far as barometer alone is concerned. There is a larger number of patients streaking in March, May and especially June than in

other months. Hemorrhage occurred more frequently in June than in any other month.

(2.) Relative humidity of high degree coincides with increased cough and chest discomfort, increased number of vesperal fevers, and increased number of bed patients.

(3.) Following weather relaxation and change from a protracted period of low glass reading wet and dry, together with high barometer, there seemed in several instances to be small epidemics of streaked sputum and occasional hemorrhages.

(4.) For seven different days in June the number of vesperal fevers rose to sixty-five and over, which is in excessive amount. Some reactions are not accompanied with humid weather. A plausible explanation is suggested, although the causative factor seems to lie outside the scope of this paper, in the fact that on several of these days visitors in large numbers, frequently over one hundred per day were visiting the patients, stirring them with family and other troubles, running over the grounds and making hard work and turmoil for all.

In this way of course there are factors not strictly meteorological which enter as a cause of variation among the indices on the plates presented. So it might be said that increased activity of patients encouraged by open weather in the spring time to walk further than they should cuts down the possible weight gain from the amount of the winter months when the heavy roads forbid extended walks. There are other reactions shown by the indices representing clinical symptoms but in a sporadic manner and apparently without definite relation to weather change. With two years' series of this sort before us more correlation may be seen.

Owing to the small lettering and complexity of these charts it is not at the present time practicable to have them reproduced among our published plates.

Many patients give a common history of onset of tuberculosis stating prodromal symptoms as in March, April and May followed by definite warning in the way of a hemorrhage or "pleurisy," "plural pneumonia," or "grippe" in June or July. This is particularly true of patients entering the sanatorium in the fall or winter months.

Accordingly, in view of the reactionary effect of the spring months upon the tuberculate it behooves one to be particularly critical of suspicious cases presenting themselves with perhaps vague signs but nevertheless real symptoms of pulmonary tuberculosis appearing in this unfavorable season.

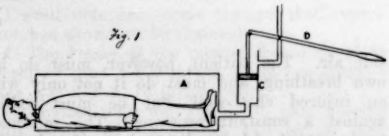
NOTE.—One object in this investigation is to afford occupation of light and congenial nature for patients such as become unhappy when confronted with the enforced idleness involved in sanatorium residence.

This work meets the requirements for and represents the collaborative effort of about ten patients some of whom are now expatients.



Mr. F. J. Bouvé, originator of the index drawings, was clearly helped in regaining health by the hearty interest he evinced for this work. Mr. Albert Young and Mr. C. W. Cushing have continued the drawings supplementing them with some added and excellent features. Misses N. Murphy, Florence Marsh, and Bessie Jean have collected much of the data on the women's wards. To these patients and to others who have helped I express my grateful appreciation for their earnest coöperation and faithful work.

N. B. B.

AN APPARATUS FOR USE IN OPERATIONS ON THE OPEN THORAX.

BY CARL A. EWALD, M.D., SEATTLE, WASH.

It is the purpose of this communication to describe a mechanical principle in artificial respiration, which the writer believes has not thus far been made use of. It may have a practical application in surgery. A in Fig. 1 is an air-tight box, having at one end an opening B, lined with an inflatable rubber tube. C is a cylinder with a piston that can be raised and lowered by a handle D. A pipe connects C with A.

The subject is put inside, the head projecting through B. The lid is made tight and the tube about the neck inflated to make an air-tight joint. When the piston in C rises, a fixed amount of air which before filled A now fills both A and C. A fixed quantity of air which before occupied say 29,000 cu. inches now fills a space of say 30,000. The air pressure within has therefore, changed from 15 pounds to 29-30ths of 15, or 14½ pounds. When the handle is raised the air in C is forced back into A and the pressure restored.

The pressure within the lungs, however, always stays at approximately 15 pounds, because the lungs are open to the outside air through the trachea. When, therefore, the pressure in A is lowered, the chest expands, and air enters the lungs. When the piston descends, the air pressure in A returns to the normal, and the lungs become deflated through the elasticity of the chest walls and of the alveolar tissue. It is possible in this way to keep up an effective artificial respiration.

Before I had finished the construction of this apparatus, a further use of its principle suggested itself,—its possible value in operations on the open thorax. The most conspicuous apparatus in this field is Sauerbruch's Cabinet. In this a constant negative pressure is maintained outside the chest while the air in the lungs is in free communication with the out-

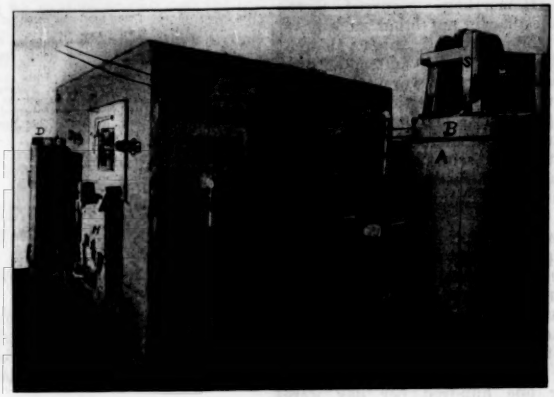


FIG. 2.

side air. The patient, however, must do his own breathing, and must do it not only with an injured chest-wall, but he must expire against a constant resistance. The muscular work instead of being directed to enlarging the chest, as in normal breathing, is done to deflate the chest, an act which in normal respiration is purely passive. These are reasons why Sauerbruch's device and the many modifications of it, including the various positive pressure cabinets, have not come into general use.

Other means have been devised to maintain respiration in the open thorax. Intratracheal insufflation is, perhaps, the most important. After reviewing them all, however, I still felt that the principle above described offered the best hope for a successful solution of the problem.

If we made our box large enough, with a pump correspondingly big, the subject with his head outside, could be made to breathe just as in the small box. The surgeon within would breathe the air of the closed cabinet. This I could show with my first apparatus,—a cabinet 6 ft. x 2½ x 1½. In the experiment I acted both as Versucher and Versuchsthier.

First I got inside the small cabinet with my head out, as in Fig. 1. When the pump was operated I could feel no change of pressure on my body, but my breathing was synchronous with the movements of the piston in spite of any moderate effort to the contrary. When I counted aloud and the piston went up, I missed a count or two until it descended.

I next closed the opening for the neck, got entirely inside, had the lid closed, and breathed the air within the box while the pressure was being changed from 15 to 14½ pounds some twenty times a minute. These pressure changes could not be detected so far as concerned my breathing. There was, however, a marked Politzer air-douche effect on my ear-drums, because obviously, the inner side of the tympanum does not feel the pressure changes as promptly as the outer side.

These two experiments showed: 1. That artificial respiration can be kept up effectively with such an apparatus allowing the anaesthetizer on the outside full access to the patient's head. 2. That the surgeon inside the cabinet feels no effect from the changing pressure except a somewhat disagreeable sensation in his ears.

I next built a cabinet 8¼ feet x 7 2/3 x 7 feet high, shown in Fig. 2. The frame was of fir scantling covered with one-inch boards and these covered with galvanized iron soldered at the joints. A window W, a door D, and an opening H for the neck, were provided and made tight with gaskets of rubber tubing. A U-tube partly filled with water recorded the pressure.

Instead of an iron pump, I used a better device,—a sheet iron cylinder B, 33 inches in diameter by 52 inches long, closed at the upper end, which moved vertically in another cylinder A, 36 inches in diameter by 48 inches high, filled with water to within 10 inches of the top. A 6 inch pipe P from the cabinet passed through the bottom of A to a height of 50 inches.

When the cabinet was closed and B then raised, part of the air in the cabinet passed into B and the pressure fell. When B descended the air within was forced back into the cabinet and the pressure restored. The work was done by a five horse-power induction motor. Three sets of iron gears reduced the speed from 1800 to 16 revolutions per minute. An iron crank 8½ inches long, carried at its end a loose iron block, which moved in a slot on the underside of a wooden lever 6½ feet long. One end of the lever was fixed. To the free end was fastened a leather strap S, which lifted B. When the crank turned the iron block mov-

ing in the slot, raised the free end of the lever 34½ inches. B returned by gravity and suction due to lessened pressure within.

A certain amount of leakage about the door and the opening for the head could not be prevented. This was found to be an advantage. The air that leaked into the cabinet when B was raised, would not all pass out again when B descended. After a few movements the pressure instead of being normal when B was down, became positive. As a positive pressure was not desired, a leather valve 5 inches square opening outward, was put in the top of the cabinet. Whatever air now leaked in was, most of it, forced out through the valve. The leakage lessened the efficiency of the apparatus somewhat, but it provided a change of air. It made unnecessary a device I had planned for filtering the air of carbon dioxide.

The volume of the air in the cabinet was 435 cu. ft. and of B above the water when up, about 17 cu. ft. We should therefore, have expected a maximum negative pressure of a little over a half pound per square inch, corresponding to about fourteen inches of water pressure. The greatest negative pressure obtained, however, was 10.2 inches. This was due 1. To the sucking in of the sides of the cabinet; 2. To leakage; 3. To friction of the air passing through the pipe. The six sides moved in a half inch at the centers when B was up. This decreased the volume of the cabinet over four cubic feet, and in effect reduced the volume of B by that amount. It accounted for most of the loss of efficiency.

The relative unimportance of the leaks was shown by opening three holes purposely left in the walls of the cabinet. A 1-inch opening reduced the negative pressure from 10.2 inches to 9.6. A 1½ inch opening reduced it to 9.3 inches. With two 1 inch and one 1½ inch openings, the negative pressure was 8.4 inches. With rigid construction, to avoid collapse of the sides, we could therefore leave an opening big enough to admit all the air needed by those inside the cabinet without greatly lessening the efficiency of our apparatus.

Experiments with this larger cabinet showed that it behaved exactly as the small one had. The subject with his head outside breathed synchronously with the movements of B, while those inside the cabinet felt nothing but a rhythmical pressure on the ear-drum and the bulging upward of the floor. Three or four persons could have remained inside for hours without difficulty of respiration. An opening that could be closed to any desired size, should be provided. This would serve primarily to regulate the negative pressure. Incidentally it would admit fresh air to those inside. A negative pressure which would be harmless to the lungs when the chest is closed, might be disastrous if applied directly to the lungs as when the chest is open. The difference of pressure which the unsupported lung tissue can safely bear must be determined by the surgeon and the opening then adjusted to limit the negative pressure in the cabinet to that amount.

Unfortunately, I was unable to do any experimental work on living animals. I secured, however, a dog at the City pound, that had just been killed by coal gas. I arranged the animal so the head was outside the cabinet and the body inside and opened the chest. The lungs were so contracted they had disappeared from view behind the engorged heart. When the motor was started the lungs were filled and deflated with perfect regularity.

From my work with this apparatus during the five weeks I had it in operation, I believe it offers a better means for the safe conduct of operations inside the open chest than any I have been able to find described. I hope it will be more fully tried out by others who have the facilities for carrying on work with living animals.

I shall note here some changes that experience has shown to be desirable:

1. The frame of the cabinet should be of fir or yellow pine 3 x 6 inches, 12 inches apart,—mine was 2 x 4, 16 inches apart.

2. Enclose with well dried 1¼ inch flooring with plenty of white lead and oil in each groove before tongue is fitted in. Give the whole two coats of paint. This will make an air-tight cabinet without use of a noisy iron covering.

3. Finish inside with ceiling or flooring nailed on diagonally to give added stiffness.

4. Size of cabinet about 11 feet x 12 x 7½ feet high.

5. Size of cylinder B for larger cabinet, 48 inches in diameter x 50 inches long, with vertical movement of 34 in. It should be of 16 gauge galvanized iron. Cylinder A should be 3 inches larger in diameter.

6. Size of pipe from cabinet 12 inches in diameter, 10 feet long, so machinery and cabinet can be put in separate rooms to avoid noise.

7. Pinion on motor shaft should be of rawhide to avoid noise. The other gears run slower and may be iron.

8. An opening in the side of cabinet 4 x 6 inches, which can be closed to any degree by a sliding plate operated from the outside or from within. This is to adjust the pressure and admit air for breathing.

9. A heavy plate glass top to admit light from above and allow spectators from suitably arranged seats, to watch operations.

The writer would be glad to give further details to any one desiring to carry on work in this field.

Scarlet-Fever in Cohasset.—Report from Cohasset, Mass., on March 29, states that scarlet-fever is at present epidemic in that town. Eight cases of the disease have been recently reported and the local schools are closed.

INSANITY IN CHINA.

BY ALFRED C. REED, M.D.,

Assistant Physician, Yale Hospital, Changsha, China.

THE question of the psychology, both normal and pathological, of the Oriental races, is of interest in two ways. It is of professional and scientific interest because it is such an untried field and offers so many alluring and wholly unknown lines of exploration. For the practice of medicine in the Orient there is imperative need of better understanding of these things not alone for the successful treatment of mental and many physical diseases but more particularly for their prevention. In the second place, the psychology of the Oriental races is of interest to the American physician because of the very practical and increasing relationship between the Orient and America, due to closer trade relations and the present tremendous awakening of Japan and China. The practice of medicine along western lines, and the introduction of modern scientific education and methods, are making rapid progress in Japan and increasingly so in China. The initial recognition of the Chinese republic by the United States has increased the Chinese regard for things American, and their desire for American customs and arts. American medicine now finds in China an opening never before presented. It will be to the advantage in a large degree of the medical profession of western countries, as well as to the great advantage of China if this opportunity is adequately met.

Aside from all these facts, the physician of all men can least afford to be provincial. Wide information must be his. Travel and knowledge gained from many lands are necessary to keep him broad-minded, energetic, sympathetic and a leader of men's thoughts.

China offers unusual opportunities for clinical and scientific investigation, and facilities are becoming available for such work. The results of such work will be applicable not only in China but also in western countries. Many problems are pressing for solution in the lines of public health and preventive medicine, clinical practice, surgery and the specialities, especially in diseases of the eye, skin and nervous system and in pediatrics. A problem can best be attacked however after it has been clearly defined. This is especially true in the realm of mental disease. If these facts hold in the United States, they are even truer in China. The pathological psychology of the Chinese is an unexplored field. There is practically no recognition or care of the insane from a public stand-point. Data are hard to get and of corresponding value when gotten. Here as in other lines, one of the primary needs in a medical way in China today is the need of statistics of incidence and local causes and characteristics of disease.

It is such considerations as these which lend special interest to a report[1] in the *China Medical Journal* by J. Allen Hoffman on patients discharged from the John G. Kerr Hospital for the Insane in Canton. Hoffman reports 312 cases discharged during the year 1912. Of these, 40% showed manic depressive insanity; 20% dementia praecox; 17.5% dementia paralytica; 3.5% exhaustive psychoses; 2% alcoholic insanities; 1.5% involutional psychoses, and the remainder scattered.

The manic depressive group showed the same preponderance of females over males which is found elsewhere. The average age of this group was 28 years, which also corresponds to figures in the United States. This was the largest group and showed the widest range of ages, from 15 to 62. Of the 125 manic-depressives, 22 showed paternal hereditary taint, 11 maternal and 4 collateral taint, a total of 30%, but more than half of the group were received through the police and no history could be obtained. Here too must be reckoned the fact that the maternal family history is often unknown. A complete record therefore would probably show the same degree of hereditary predisposition as in the United States. Among the vicious habits of the parents of these cases opium addiction and alcoholism were more common than in any other group. Venereal disease in the parents was rare. Manic depressive insanity often seemed to follow some season of festivity and drinking, and was especially common after the Chinese New Year. 28% of these cases gave a history of previous attacks. The results of treatment were not different from those at home. 61% were discharged cured, 24% improved, 8% not improved and 6% died.

As in the United States, dementia praecox is of frequent occurrence, forming 20% of Hoffman's cases. In this group there were over four times as many males as females. The average age of onset was 18, the actual time varying from 15 to 24 years. The hebephrenic type was most frequent and usually appeared in young men of the better class families socially. The paranoid type was less frequent and appeared at a somewhat greater age. Hereditary predisposition seems to be the great causal factor in South China. Opium addiction and alcoholism were of frequent occurrence in the fathers of these cases, and seemed to have a special influence in favoring mental weakness in the children. In many of these cases the exciting cause of the disease was in some way associated with the sexual life of the individual. Hoffman notes the fact that a surprisingly large number of cases of dementia praecox which in the United States are adjudged hopeless outside of an institution, in China are able to make a livelihood and return

[1] Hoffman, J. Allen: A Report of Patients Discharged from the John G. Kerr Hospital for Insane During 1912. China Medical Journal, November, 1913, p. 369.

to their homes. The easy-going leisurely pace of ordinary Oriental life is responsible for this, as is also the absence of the mental stress, competition and hurry of America. We see here a practical illustration of the mental results of the two environments.

Of Hoffman's cases, the third largest group was dementia paralytica, and in this group were four times as many men as women. While syphilis is wide-spread in China, the strange fact remains that dementia paralytica and other para-syphilitic affections are rare. In explanation of the high percentage of this disease at the John G. Kerr Hospital, Hoffman states that these cases were largely among persons who had travelled outside of China, some as coolies, some as merchants. They had been subjected to various hard-ships at sea, and were addicted to venereal excesses as well as to alcoholism or opium. All who could give a history, had contracted syphilis abroad, especially in Macao, the Malay states, Borneo, the Philippines and North and South America. Among the southern Chinese who have never left their own country, paresis is uncommon. The author points out that it is a subject demanding investigation as to whether syphilis alone is responsible for dementia paralytica, or whether other factors such as debauched living and the stress of the competitive western life enter in also. Or the syphilis of the Orient may be caused by a spirochaete of a different strain which does not tend to produce para-syphilitic affections.

Of the eleven cases of exhaustion psychoses, nine were in men and only two in women, just reversing western statistics, but explained by the shock of fear and exposure during the war of rebellion of that year. Alcoholic psychoses ranked fifth in number, though Hoffman considers them to be increasing. In five years in China, he has seen but one case of delirium tremens.

The opium habit was responsible for very few of this series of cases, but Hoffman reports having found whole families of children who were imbeciles, idiots, or dements, and in whose history the only causal factor apparently was opium addiction in the father.

The conclusion is reached that insanity is as common, if not in fact more common in South China than in the west. One strong contributory factor to this condition of affairs, is the custom of ancestor worship which demands that every male must have off-spring. Even demented persons are at times taken out of hospital that they may marry and beget children. Naturally this results in a greater increase of mental disease among the wealthier and better classes than among the poor who often can not afford to marry.

Three facts deserve special mention in a consideration of the prevalence and varieties of mental disease in China. Both are substantiated by the witness of many observers. The first is the absence to a great degree of alcoholism as a common vice except in the coast-wise cities. This largely removes the influence of alcohol as a hereditary factor in the development of mental disease, and in the production of mental defectiveness. At the great festival of the Chinese New Year, over-indulgence in alcoholic beverages is more common as it is also on other gala occasions. But as a chronic common vice, it has nothing like the prevalence found in western countries. The second fact is the frequency of syphilis in the primary, secondary and tertiary stages and the extreme infrequency of para-syphilitic conditions. It is a matter of clinical observation that arterio-sclerosis and thickening of the arteries is excessively common. Aneurysm however is rarely seen. Hemiplegia from embolism or thrombosis is frequent while tabes and paralytic dementia are quite unusual.

The third fact of special interest is that while conditions of heredity, opiumism and alcoholism, the latter chiefly in the coast cities, favor the development and increase of mental disease and defect, and while these diseases are probably as frequent in China as in America, nevertheless the lack of the stress and strain of life in America makes the results of such disease in many cases far less serious than the results of similar conditions in America. It is easier for the weakened mentality to take care of itself and be independent in China because of the machine-like routine of the ordinary life of the people and their freedom from exciting and disconcerting agencies of various sorts which in other countries are all too common. It must be noted too that there is more than a little truth in the often made observation that the Chinese differ in their nervous make-up from Occidental races. They often seem indeed to be devoid of nerves and utterly unaffected by and oblivious to, many things which a western man finds not only irritating but really unbearable. This placid disregard for things we usually associate with "nerves" must have a more or less important bearing on the development of latent causes of insanity. At present it is impossible to estimate this influence, but it is very real and ought to be an able adjunct if properly used, for the prevention of functional insanities whose out-break depends on some exciting cause in the immediate environment of the patient.

The student of heredity finds a rich field in China where genealogies are so carefully preserved. Many old families appear to be dying out, their energies and vigor dissipated, and some of the reasons lie close at hand. Too close inbreeding is not a factor, because of the deep repugnance and even prohibition of marriage between persons even distantly related. Usually the same surname, even where no blood relationship exists, serves to prevent marriage. But on the other hand, every male is virtually forced to have off-spring and the belief is well-nigh universal that daily sexual intercourse is

necessary for health. The debilitating effect of this and the gross moral tone of the people as a whole, has much weight in the perpetuation of poor and defective stock. Coupled with this is the fact that tuberculosis in every form is rampant and that venereal disease is rapidly increasing. It is evident that the percentage of mental defectives and insane would reasonably be high.

Under the new government, republican in name at least, China has great possibilities. Not the least of the necessities for her advance, is the development of public health work and the investigation of her great medical problems. If western nations like America are only now just awakening to the close relation between economic efficiency and public health, it is small cause for wonder that China with her inherent belief that human life is her cheapest commodity, should not yet have appreciated such a relation. The near future however promises to show a great advance both in the popular recognition of such things by the Chinese, and also in active measures to remedy existing conditions.

EDUCATIONAL STANDARDS FOR NURSES. STATE REGISTRATION AND TRAINING SCHOOL INSPECTION.

BY SARA E. PARSONS, R.N.,

Superintendent of Nurses, Massachusetts General Hospital.

UNDOUBTEDLY the standards for nursing education set by the American Red Cross is the most important fact in the nursing field today. All nurses with a spark of patriotism desire to be enrolled for the service of their country in time of war or calamity. Any school that would have the future welfare of the country at heart must desire to equip its pupils to meet the national standards. The school that pursues any other policy is, in my opinion, pursuing a suicidal course.

No one but a reliable woman with good moral standards and a complete all around training ought to be enrolled for active service, as no one can predict what phase of illness a nurse must deal with in Red Cross emergencies. The War Relief Board of the American Red Cross has created a national committee of fifteen to establish a uniform standard of qualifications to govern the enrollment of nurses. The committee in full is as follows: Jane A. Delano, R. N., Chairman; Mabel T. Boardman; Mrs. William K. Draper; Major R. W. Patterson; Dr. T. W. Richards; Dr. William Welch; Mrs. Frederick Tice; Emma M. Nichols, R. N., (City Hospital, Boston); Alma E. Wrigley; Mrs. Whitelaw Reid; Anna C. Maxwell, R. N., Isabel McIsaac, R. N., and Julia C. Stimson, R. N.

What are the requirements, and are they just?

TRAINING. The nurse must have had at least a two-years course of training received in a general hospital which includes the care of men and has an average of at least fifty patients during the applicant's training. In cases where subsequent hospital experience, or a post-graduate course would seem to supply any deficiency of training, applicants may be enrolled with the approval of the National Committee.

Graduates of State Hospitals for the Insane are not eligible unless their experience includes at least nine months training in a general hospital either during their course of training or subsequent thereto. In states where registration is required by law graduates of schools not meeting the requirements of the State Board of Registration will not be considered eligible for enrollment. Applicants must have the endorsement of the American Nurses' Association and of the Training School from which they graduated.

They must be at least twenty-five years of age.

It will be noted that an applicant may make up her deficiencies by post-graduate work so that these standards cannot be said to be unreasonable.

In view of the general ethical reasons why nurses should be adequately prepared for the profession they voluntarily assume, is there any just objection to an inspection of training schools by some properly qualified person appointed for that duty by the State Board of Nurse Examiners?

Is there any good reason why such an inspector should not be selected from nurses who meet at least the minimum standards set by the National Committee?

Is there any logical reason why hospitals that undertake to run training schools should not stand in the community for what they really are?

If they wish to meet national standards why should they not affiliate to make up their deficiencies as most recognized schools today are obliged to do?

Some of the largest and best-known schools in Boston are dependent upon smaller and special institutions to give their pupils experience which their own wards cannot supply. The Boston City Hospital, the Massachusetts General and the Peter Bent Brigham are good examples of the large hospitals that affiliate, and the Children's Hospital and the Adams Nervine are notable examples of what small special hospitals can do for their schools when determined to meet definite standards.

It is both difficult and expensive to maintain a good training school, but most hospitals find that it pays in results.

New York hospitals that wish to maintain training schools eligible for registration with the Board of Regents must give at least a two years course in a hospital or hospitals giving definite kinds of experience, and the schools must submit to the Regents papers to show that applicants have had at least one year in high school *or an equivalent* before entering the school. It is this last requirement that seemed to cause so much controversy between medical superintendents of hospitals and the nurses who stand almost unanimously for such standardization, (although they would prefer higher standards and intend to raise the educational requirements.) Women with less education than that must make up their deficiencies if they wish to care for the sick in New York as registered nurses.

To train, graduate and register women of such a low standard as a grammar school education implies an imposition on the public (that eventually pays for it in dollars) that is not to be endured.

The position of nurses as a body who are insisting on better education and better opportunities needs no defense in the mind of any thoughtful man or woman, but the plea made by a few who are loud in their cry for no restrictions on those who go into the hospitals and homes to nurse the sick is sometimes so plausible as to persuade those who do not carefully think out the whole situation.

Opposed to the names of men who are quoted as objecting to state registration for nurses; for training school inspection, etc., there are hundreds of notable men and women who endorse the movement.

May I quote from a letter recently sent me by a hospital trustee of another state who has recently become interested in the nurses educational movement—

"Small hospitals with training schools that are designed by Boards of Trustees for utilitarian purposes have much to answer for. Too many training schools are issuing diplomas that in substance certify to residence for a continuous term of months at some hospital where the holder has been a very satisfactory maid of all work.

"The laymen, who constitute the governing boards of hospitals that maintain training schools, have not been impressed with the moral obligations they assumed when inviting a young woman to enter the training school. The uppermost thought has been that it was an inexpensive and accepted method of paying for the care of sick people dependent on charity.

"Much good can be accomplished if an organized educational campaign could be conducted in the ranks of the laymen who govern the hospitals. Thousands of these well intentioned conscientious men are big in their business world but small in the knowledge that covers the subject of nursing education. I have been in hospital work very actively for twelve years and when I think of the utter ignorance of nursing education that blinded me for nine years I wonder what use I made of my eyes and ears.

"In detail this letter may not interest you, but its chief point is that you can readily see that an officer of an obscure country hospital has been awakened by the echo of the gospel that earnest women of the nursing world have been preaching."

The above letter speaks for itself. There is at present in Boston a progressive, humanitarian movement on foot to provide nursing and household care for people of moderate means, (Household Service Bureaus.) The Women's Municipal League is behind it, and a committee of its members, doctors and nurses are framing a curriculum, and searching for hospitals where attendants may be taught to do this much needed work. Such attendants may be of untold service in the community if provision is made so that the general public may readily distinguish between the trained registered nurse, and the attendant.

For the success of this project which is one of the most important social movements of the present day it is important that the State Board of Nurse Examiners be empowered to inspect training schools so that the registered nurse of the future in Massachusetts may stand before the public as one who has had sufficient practice and theory to warrant confidence when people wish to employ a trained nurse.

The attendant should also meet certain definite standards and be licensed or registered to practice. She will not take the place of the trained nurse any more than the trained nurse takes the place of the doctor but she will supplement the work of both.

In hospitals where the problem of training nurses for registration is too difficult we should find the laboratory for the training of attendants.

All persons who are interested in the 90% of the population who most need consideration will, it is hoped, help the trained nurses and the Board of Nurse Examiners to get their training school inspector, and also support the effort to provide the community with trained attendants.

HOSPITAL BEQUEST.—Under the will of the late Frederick Townsend Martin of New York $5,000 is left to the Albany Hospital, Albany, N. Y., to endow a bed in memory of his mother.

CASES OF INFECTIOUS DISEASES reported to the Boston Board of Health for the week ending March 31, 1914: Diphtheria 46, of which 4 were non-residents; scarlatina, 130, of which 13 were non-residents; typhoid fever, 3; measles, 92, of which 1 was non-resident; tuberculosis, 50.

Clinical Department.

TREATMENT OF HEMORRHAGIC DISEASES.

BY H. GILDERSLEEVE JARVIS, M.D., HARTFORD, CONN.

Assistant Surgeon to the Hartford Hospital.

IN past years little progress has been made with the problems of the etiology and the treatment of hemorrhagic diseases. The etiology still remains an obscure subject, as two diametrical opposite opinions are held as to its cause:

1. That an abnormal vessel wall allows normal blood to escape through it.

2. Abnormal blood because of its abnormality is able to pass through a normal vessel wall.

The arguments in favor of either supposition are not as yet convincing, although the preponderance of evidence seems to be in favor of the latter view; that something which causes the blood to coagulate is missing. In the cases tested there seems to be a diminution in the number of platelets, and in the first case we were able to foretell an outbreak of purpura by the diminution of platelets. The coagulation time has been quite variable, 3-10 minutes up to 40 seconds in cases which seemed to be clinically the same.

The mortality was quite high when the older methods of treatment were in vogue. The combined statistics of Schloss, Commiskey, Vassmer and Shukowsky show a mortality of 50.3%. According to Vincent, taking all forms of the disease, probably 60% represents the average mortality.

The older methods consisted of the use of various therapeutic agents, *i.e.*, adrenalin, calcium chloride and lactate, tannic acid preparations, ferric preparations and gelatin. These agents were on the whole quite disappointing, although gelatin has been highly recommended by German writers and has been widely used in Europe. Vassmer reports 34 cases of melena neonatorum treated with gelatin, with a mortality of 8.8%.

NEWER METHODS OF TREATMENT.

The method of blood transfusion was introduced and was employed by Lambert, Carrell and Brewer in 1909. Lespinasse and Fischer in 1911, with their own cases and others, collected in the literature, reported a total of six cases with a mortality of 33 1-3%. Vincent, in 1912, reported 11 cases, 8 of which were successful. Bernheim had one successful case. He devised two metal tubes, one of which is inserted into the vein of the recipient and the other into the artery of the donor. When both are in place they are united. This method and that of Vincent with the glass tubes, makes the technic easier because it allows more room between the two patients. Vincent has made one improvement over the technic of others in the use of the external jugular vein, as it is the largest of the superficial veins in the baby.

There were also various modifications of the direct transfusion method as practiced by Kimpton, Lindeman and Vaughn.

A second treatment that came into vogue was the injection of animal serum. This was first suggested by the work of Weil on hemophilia. The serum was generally obtained either from a horse or a rabbit. The amount used was 10 c.c. up to as high as 100 c.c. at a time and repeated. Leary, Bigelow and others used it with fair success. This treatment was not confined to the hemorrhagic diseases of children, but was utilized in various conditions, such as tonsillar hemorrhage, uncontrollable bleeding from jaundice, hematemesis and even hemoptysis.

The third method was the use of human instead of other varieties of serum. Welch, in the *American Journal of Medical Science* for 1910, first brought out this idea. He reported 13 cases, all of which he cured this way. Last year he reported 32 cases; some of which were hemorrhagic cases, others were just septic, in which he used normal blood serum with what he called brilliant results. He gives no detail report of the cases nor of the per cent. cured. In conclusion he states, "Of other conditions in which I have had experience in the use of human serum, the various bleeding conditions rank first, and of these, more especially the hemorrhagic condition of the new born."

In considering the use of sera or blood transfusion, four points were impressed upon me:

1. Dexterity required as in a transfusion. Men have to be specially trained in the surgery of blood vessels to do this.

2. Danger, as from thrombosis.

3. How did we know that just the elements of the serum were missing?

4. Various articles are necessary to do a transfusion or even in the use of sera.

METHOD EMPLOYED.

To obviate the drawbacks mentioned above, I have employed the so-called injection of whole human blood. Schloss and Commiskey, in two articles during 1911-1912, reported nine cases with a cure of seven. Myers, of Wisconsin, had two cured cases. I took up this method about two years ago, starting in the pediatrical clinic of the Hartford Hospital, and up to date have had thirteen cases.

Of all the methods which have been advocated in the treatment of hemorrhagic diseases, this one is by far the simplest. The only apparatus needed is a syringe, needle and a piece of strong flexible rubber. The latter is not absolutely necessary. The syringe should hold at least 10 c.c., preferable 20 c.c. of fluid. Those made

entirely of glass are better because in these the blood is less likely to clot. The needle which has given the best results is a medium size aspirating needle. The piece of rubber joins the needle to the syringe and allows play between them, so that if the child squirms around, the needle is less likely to break off or injure the child.

The areas from which the blood is taken and where it is injected, must first be carefully sterilized. The blood is drawn from the basilic vein at the elbow, preferably from the father or some male relative, although on several occasions it has been taken from the mother as she lay in bed. It is then injected into the buttocks or back of the infant. The amount used is from 10 to 20 c.c., and is to be repeated in 4 to 6 hours if the hemorrhage is severe or if there are any signs of new bleeding. I always repeat it if purpura is present.

I will now briefly cite my thirteen cases:

Case 1. A. R. Admitted to Hartford Hospital on October 8, 1911.

Complaint. Swollen face and loose bowels.

June 1, 1912. A summary of this case shows numerous attacks of purpura, a continued emaciated condition complicated by pneumonia, double otitis media, perineal abscess, varying periods of general edema, rhinitis and at times the child has been in a critical condition.

Because of his hemorrhagic condition, 20 cc. of father's whole blood were injected into the patient's buttocks.

June 17. Because of another slight outbreak of purpura, 20 cc. more of father's blood were injected.

July 1. Child has gained steadily in all respects, but because of one small purpuric spot on the right thigh, 20 cc. of blood were again injected.

August 15. No more purpuric outbreaks, child has gained steadily, is able to walk and was discharged well.

Case 2. C. P. Age 4. Came to my office for severe nosebleeds and spots over body. For two and one-half years has been subject to outbreaks of purpura and severe nosebleeds. This has been getting worse and last week the patient had an outbreak every day. Mother states that the bleeding is so severe that the child faints. On examination no ulcer was found in the nose, but the child was very anemic and purpuric spots were present on the left thigh and right leg.

15 cc. of father's blood were injected. Bleeding stopped immediately. In a week, two drops appeared at the nostril. 15 cc. of father's blood were again injected.

Feb. 15, 1913. Child was lost sight of. Since last note, the child has had one attack of nosebleed, but the father refused to have it treated any more.

Case 3. Baby Oliver, 6 weeks of age. For past three weeks has had bleeding from nose, gums and rectum. During the past two days, there has been bleeding from the cord and into the brain and orbital cavities. Examination shows a comatose child, fontanelles very tense, marked protrusion of right eye ball and bleeding from gums, navel, nose and rectum. Purpuric spots over rectum, thighs and upper extremities. Child practically moribund. Twenty cc. of father's blood were injected. Child died in four hours.

Case 4. Mary R., 3 weeks old. Came to my office Sept. 1, 1912.

Complaint. Bleeding. Mother stated that the child had bloody stools for about three days. On examining child, it had a rather free discharge of bright blood from the rectum. The rest of the examination was negative except for anemia. Hemoglobin 65 per cent. Coagulation time, 10 minutes.

Twenty cc. of mother's blood were injected into child's buttocks.

Child made an immediate recovery, gained steadily in weight and never had any more bleeding.

Case 5. Lillian W. Entered Hartford Hospital on November 22, 1912. Age 2 months. Past history negative.

P. I. One week ago baby began vomiting after feeding, sometimes curds and at other times liquids. Baby has been nursed every time she cried, either from breast or Eagle Brand Condensed Milk. Bowels irregular, at times 2 to 5 movements a day, green, watery, with some curds and mucus. Child has lost about one and one-half pounds since birth.

Examination. Crusts on scalp. Pharynx, chest and abdomen negative. Small umbilical hernia, recents loss of weight, skin clear.

Nov. 26, 1912. This infant has not been doing well. At first, while it took its feedings yesterday it had renewed vomiting and whereas there were noticed some bright blood clots in the stools on the 23d; to-day there is considerable bright blood in the faecal discharge and the child's general state is much depressed. Rectal examination, including an abdominal palpation, fails to reveal any cause for bleeding.

Ten cc. of father's blood were injected into child's back. Bleeding was immediately controlled.

Jan. 4, 1913. There has been no further bleeding and the infant has continued to improve and has gained two and one-half pounds. It is now on a milk formula and with the exception of slight eczema of the right ear, creases in neck and groin, there are no further abnormal developments.

Case 6. Baby B., 3 days old. Seen in Wallingford, Conn.

No bleeders in family. On second day after birth, diapers were red and again on that night there was slight bleeding from one nostril. No other foci of hemorrhage.

Examination. Well developed child. Blood clot in left ear and right nostril. Active bleeding from vagina and navel. Slight purpuric hue to entire skin.

Eighteen cc. of whole blood from paternal uncle were injected into child's buttocks. Blood was taken from the uncle because the father had been in poor condition. Bleeding immediately stopped and child has had no recurrence.

Case 7. Peter F. Admitted to Hartford Hospital on Feb. 23, 1913.

Complaint. Hemorrhages from nose.

Born November 16, 1912, full term, normal delivery. Weight, 9 pounds. Always breast-fed. Always well until present illness. Three days ago child had nosebleed from left side. Some was swallowed and a clot 1½ in. x ½ in. was vomited, also some very dark vomitus. Black stools for two days,

but no more vomiting. Stools were better yesterday and to-day, O.K. (yellow). Child did not nurse well this morning.

Father living (recovering from an operation). Mother living and well. No bleeders. One other child, O. K.

Feb. 23, 1913. Eight c.c. of serum from mother injected into child's buttocks.

Feb. 24. This infant is in a precarious state, somewhat stupid, right external strabismus. Tense fontanelle, peculiar pallor, semi-tonic state. Throat, chest and abdomen negative. There are no purpuric spots present, although on the right knee the skin is a little dusky.

Feb. 24, 5 p.m. Because of the precarious condition and duskiness of skin, 10 c.c. of whole blood from father were injected into the buttocks of the child.

Feb. 25. There is a slight increase in the intercranial pressure this morning. Fontanelle more tense. Eyes held in a staring, inattentive gaze, and except when the child is aroused, it remains in a semi-conscious state in which the eyes are partly open. There still remains the tonic state of the musculature. On the other hand, a stool just passed contains no blood.

Feb. 26. There has been no further evidence of hemorrhage. The fontanelle is the same as yesterday. The tonicity is a little less and the child responds to external stimuli; but when left, it returns to its semi-stupid condition in which the eyes still tend to be fixed, but less so than formerly.

March 1. The baby is less stupid today. Its pupils respond readily. There is still a little internal strabismus. The neck is a little stiff and the fontanelle tense, but less so than yesterday.

March 16. The improvement has been very rapid and satisfactory and today there is no evidence of intracranial pressure. Child is clear in its mind and improved in nutrition. It is on a milk formula supplemented by breast feedings. General physical examination negative.

CASE 8. Joseph P. Admitted to Hartford Hospital on March 20, 1913. Age 20 months.

Complaint. Severe epistaxis on March 17, 18 and 20.

Family History. Father and mother well. No other children. Mother 22½ years old; has had considerable epistaxis during the hot weather for the past few years, but not as a child. No known tendency to hemorrhage on maternal or paternal side of family.

Past History. Child born at full term, normal labor, well developed. Breast fed for 14 months. Since then it gets "everything." Bowels move normally, stools are soft, yellow, no curds. No vomiting except when taking breast feedings too quickly in early infancy. Always well up to present illness.

Present Illness. March 17, at 4.30 p.m., while in mother's arms, child's nose began bleeding quite profusely, lasting 55 minutes. Stopped by cold water compresses on neck.

March 18 at 2 a.m., began to bleed profusely from nose. Mother could not stop the hemorrhage and a doctor was called. The hemorrhage continued intermittently until 1 p.m. Baby then looked weak and pale.

March 20, at 2 a.m. began to bleed again and lasted until 6 a.m., stopped spontaneously. Two dark, bloody stools. Question of bloood from right ear today (March 20).

This infant presents three prominent symptoms: First, as regards it skin; it is unduly pale and the child's face, particularly the upper lip, is puffy. There are purpuric areas on the lower extremities from the knee down.

Secondly, there is evidence of recent hemorrhage from the left nostril. On the other hand, the post-pharyngeal examination reveals no blood. Thirdly, the child presents a peculiar, weak and dyspneic condition, there being no chest findings to account for it. In addition, it has a slight cough. Throat, chest and abdomen negative. Phimosis present. Child tends to lie in an exhausted and semi-stuporous condition after having been examined.

March 20, at 2 p.m., 19 c.c. of father's blood were injected into child's left buttock.

March 20, at 8 p. m., 25 c.c. of father's blood were injected into right lower back.

March 21. Small petechiae are present on legs and feet and a few on the forearms. The area over the right knee is increased and a new one has appeared over the left ilium. Generally the boy is better. The breathing is less labored, although abnormal still, and the child is a little brighter.

March 21, at 2.15 p.m., 20 c.c. of father's blood were injected into right buttock.

March 21, at 8 p.m., 20 c.c. of father's blood injected into back.

March 31. Purpuric condition has entirely cleared up.

CASE 9. S. A. G. Seen March 20, 1913. Three days old. Day after birth a right-sided cephalohematoma was noticed and dark blood in mouth, and there began to slowly appear purpuric spots over the backs of the hands and both lower legs. Forty-eight hours after birth, the child vomited dark blood, and stools looked darker than normal. Examination shows a moderate sized right sided cephalohematoma, purpuric spots on back of left hand, over both lower legs and right shoulder. Ten c.c. of whole blood from father were injected into the child. Child had a very dark stool while this was being done. Next day it appeared quite well, nursed well and stools were normal. Because of a new spot, 10 c.c. of whole blood again injected. Not seen the next day.

March 26. Child again seen. Very stupid and refuses to nurse. Several new spots have appeared. Ten c.c. of blood again injected.

Child gradually failed and died the next day. (Attending physician's note.)

CASE 10. July 15, 1913. R. T., 7 weeks old. Poorly nourished. Vomited almost everything for about four days. During last two days purpuric spots have appeared over abdomen and bright blood has been passed per rectum. Twenty c.c. of whole blood taken from a nurse and injected into child's buttocks.

July 22. Bleeding has stopped and child is gaining weight on a milk formula.

CASE 11. Seen at St. Francis' Hospital, Sept. 14, 1913. Three days old. Bleeding from ears, mouth and nose. Forceps case. At first it was thought that the bleeding was due to this, but when I saw the case, the bleeding was from other places. Child was in a very critical condition.

Twenty c.c. of father's blood injected into child's thigh. Child grew steadily worse and died in two hours.

CASE 12. Mrs. W. W. C. Age 38. Two months pregnant. Because of poor physical condition it was deemed necessary to abort. This was done. She bled profusely, and inside of four days was packed and repacked eleven times, with no apparent good result. At this point 20 c.c. of her husband's blood were injected into her buttocks. In two hours the packing was removed with no bleeding. She has not bled since then.

CASE 13. December 24, 1913. R. P. Age 8 days. Three days ago, impetigo began to appear over body and there was bleeding from the rectum, navel and left ear. Bleeding had been increasing and because of this, 20 c.c. of the father's blood were injected into the child's buttocks.

Dec. 25. All bleeding had stopped, except a little from the rectum.

Jan. 1, 1914. No more bleeding, impetigo better.

MORTALITY.

In this series of 13 cases which have just been reported, there were 3 deaths, or a mortality of 23%. If we take the combined statistics in the literature of the cases so far reported, that have been treated by this method, we find that there were 5 deaths in 24 cases, making a mortality of 21%. The four cases reported by Vincent are not included, because as he states, "I did not use the method as recommended, and consequently these cases are not a fair test."

The transfusion method, taking the combined statistics of Lambert, Carrell, Brewer, Bernheim and Vincent, shows a mortality of 29%.

The mortality of cases in which human sera were used cannot be given exactly, because the writers on this subject did not give their cases in detail.

If recognized and treated, these cases do not, as a rule, die from the loss of blood, but from the mechanical effect of the hemorrhage into some vital organ. In concluding, I would like to impress upon your minds the following three salient facts in favor of the injection of whole human blood in the treatment of hemorrhagic diseases:—

1. Simplicity of employment.
2. Efficaciousness.
3. Lack of danger to either recipient or donor.

So it seems to me that we now have within the scope of every practitioner, a method to combat more successfully this heretofore rather fatal disease.

In conclusion, I wish to thank those doctors who permitted me to see some of these cases and especially Dr. Charles A. Goodrich for his helpful aid and suggestions.

A CASE OF FRACTURE OF THE CARPAL CUNEIFORM BONE.

BY WM. PEARCE COUES, M.D., BOSTON.

Isolated fracture of the carpal cuneiform is of extremely rare occurrence. The special fracture text books make mention of the possibility of its occurrence without citing cases as a rule; and general surgical works make no mention of it in their pages. Fracture of the carpal scaphoid and dislocation of the semilunar quite naturally, on account of the frequency of these injuries, have been carefully studied and described even since the advent of the x-ray.

History of Case: Miss F. L., 23 years, was seen Nov. 11, 1913. The history was as follows: While doing gymnasium work, she met with the injury which we describe.

Aug. 16, 1913, while standing on the hands she turned too far, lost her balance, fell to the ground, rolled over on her left hand. The hand was flat, extended on the ground. Immediate pain was felt in the wrist and she was unable to use the hand afterward. She says she felt crepitus at this time. The next day the hand was very lame and there was ecchymosis over the dorsum of the hand, which lasted a week or more. Monday, she consulted a physician who thought there was no fracture. The hand was bandaged and liniment prescribed. Ever since then there has been disability, felt most in rotation of the wrist or extension of the hand. Pain on extension is most marked over the second metacarpal. The pain was constant at first; then only when attempting to do her work, but there has been no time when she has been able to do her gymnasium work without pain. Of late, numbness of the hand and arm was felt.

Examination. Well-developed, active, rather slight young woman. Examination of the wrist

Fracture of Carpal Cuneiform.
November, 1913.

Fracture of Carpal Cuneiform.
January, 1914.

showed the following: There was no obvious swelling or ecchymosis noted in the region of the cuneiform. Flexion and extension of the wrist is slightly painful in the region of the cueiform bone. There is very slight pain in adduction of the wrist; in active abduction there is more pain. Forced passive abduction of the wrist causes great pain in the region of the cuneiform. Flexion and extension of the fingers is not painful. Rotation of the forearm causes pain in the wrist in the region of the cuneiform and slightly lower. There is a very slight synovitis of the middle extensor tendon, showing at the middle of the back of the hand. When the patient picks up a weight or turns a door knob the pain is felt in the wrist in the cuneiform region. Direct pressure over the cuneiform is very painful; but no crepitus is elicited. Lateral pressure across the wrist in such a manner as to make the pisiform press upon the cuneiform bone, causes much pain. The x-ray showed a fracture of the carpal cuneiform incomplete, running from the ulna side about half way across the bone obliquely. Hand immobilized on palmar splint with pad and strapping over the cuneiform. There was considerable relief experienced after the hand had been immoblized for a few days; and from this time, there was progressive improvement which, however, was slow. Two weeks after the first radiograph, a second was taken which showed no union of the crack. Another radiograph was taken in another two weeks, after fixation for about one month, which still showed no bony union; though the pain and disability were much less. The next radiograph, taken in about ten days, showed considerable union. At this time the splint was removed and the hand bandaged. Examination showed at this time practically no tenderness over the cuneiform, no thickening, and movements of the wrist were executed without pain. Picture taken the middle of January, 1914, nearly two months after the first picture showed union practically complete. A faint line could still be seen. Since this time patient has been using the hand cautiously without trouble or pain of any sort and examination shows practically no more tenderness over the cuneiform of this wrist than of the uninjured wrist.

Interesting points in the case are: The length of time of the disability and pain, without recognition of the nature of the trouble, and the somewhat long period of fixation necessary before union and a cure was effected. This undoubtedly was due to the length of time that the patient had attempted work with the hand, with the fracture still ununited.

Medical Progress.

PROGRESS IN MEDICINE:—RECENT ADVANCES IN CERTAIN BLOOD DISEASES.

BY ROGER I. LEE, M.D., BOSTON.

PRIMARY PERNICIOUS ANAEMIA.

ONE of the many theories of the etiology of pernicious anemia has been that some hemolytic substance is elaborated in the intestinal tract perhaps from the mucous membranes or from some of the fatty acids. McPhedran[1] in a careful study of the hemolytic properties of fatty acids and their possible relations to the causation of toxic hemolysis and pernicious anaemia concluded that hemolysis by liberation of specially hemolytic fatty acids from the fatty complexes of disintegrating cells is not supported by evidence. None of the fatty acids were more toxin than the common oleic acid. Ewald and Friedberger[2] found no hemolytic substance from the mucous membranes of cases of pernicious anaemia.

Splenectomy in Pernicious Anaemia. A certain amount of evidence has been introduced by Banti,[3] Eppinger[4] and others, tending to show

that in pernicious anaemia there is increased hemolytic activity of the spleen. One result of the introduction of this evidence has been the removal of the spleen in certain cases of pernicious anaemia. Eppinger reports seven cases. Klemperer[5] reports ten cases, Mosse,[6] Huber[7] and others, report isolated cases of splenectomy in pernicious anaemia. Most of the cases were reported as improved after splenectomy. In Klemperer's series of ten cases there were two deaths; eight were benefited with one clinical cure.

Splenectomy in pernicious anaemia certainly has some basis on theoretical grounds. On the other hand—the case reports while showing uniformly considerable improvement, fail to arouse much enthusiasm. It is of course too early to pass critical judgment on any therapeutic measure in a disease that runs such a bizarre course as pernicious anaemia.

Salvarsan in Pernicious Anaemia. Inasmuch as arsenic has been advocated for so many years in pernicious anaemia, it is not remarkable that the literature contains some reference to the use of salvarsan in this disease. Boggs,[8] Bramwell[9] and a few others report remarkable improvement in the blood picture of pernicious anaemia shortly after the use of salvarsan. Their favorable experience has not been widely confirmed.

Transfusion in Pernicious Anaemia. Vogel and McCurdy[10] have studied the effect of blood transfusion and regeneration in pernicious anaemia. They give an extensive bibliography. They advise the repeated intravenous administration of rather small measured amounts of blood.

Weber[11] has advised the repeated intramuscular injection of fresh blood in small amounts for all forms of severe anaemia.

Radium in Pernicious Anaemia. Radium has been advocated as a therapeutic agent in all forms of blood diseases including pernicious anaemia. The literature on the subject of the therapeutic use of radium is very confusing. Radium in the form of thorium-x had at first many enthusiastic advocates. Of late, particularly in pernicious anaemia there is a tendency to urge caution in the use of radium preparations and many unsuccessful cases are reported. Meseth[12] gives a resumé of the literature and reports two personal cases of pernicious anaemia unaffected by thorium-x. v. Benczur[13] thinks that pernicious anaemia is favorably influenced by thorium-x which seems to him more effective than arsenic. The only safe conclusion from the evidence to date is that the radium preparations especially thorium-x are not harmless agents in the treatment of pernicious anaemia and that improvement is not the rule and even reported cure is rare.

Splenic Anaemia. The literature continues to be crowded with case reports of splenic anaemia. Most of these cases have been operated and are recorded as clinical cures after splenectomy. The fact now seems established that cases of anaemia and splenomegaly without apparent cause are usually cured by splenectomy. Giffin[14] from the Mayo clinic reports clinical observations on 27 cases of splenectomy. Splenectomy was done in 18 cases of splenic anaemia. Erdmann and Moorehead[15] in discussing the subject of splenomegaly (Gaucher type) review the mortality of splenectomy for various conditions. They believe that the mortality with the present surgical technic should not be over 10%. Erdmann and Moorhead give a good bibliography of splenomegaly (Gaucher type) and report two cases of their own. Splenectomy was done in one case with apparent cure.

Confusion still exists as to the classification and interrelationship of the various anaemias with enlarged spleens. A large number of cases of splenic anaemia of the congenital family type with hemolytic jaundice have been described. Some of the cases of hemolytic jaundice certainly occur as a family group. In others no family history can be obtained.

Haematogenous Jaundice. Richards and Johnson[16] and many others report carefully studied cases with jaundice, splenomegaly, lowered osmotic resistance of the red cells, anaemia with typical staining reaction of the red corpuscles, and urobilinuria. A number of cases of apparent cures in this condition are reported following splenectomy. All the writers, however, point out the fact that the patients with this condition seem very little troubled with it and splenectomy seems a rather radical therapeutic measure for a disease that interferes but slightly with the patient's activity.

In so-called Banti's disease splenectomy is advised by Banti[3] himself and a number of apparent cures are reported after splenectomy. Klemperer and Hirschfeld[4] report one case of splenomegaly and anaemia that developed polycythaemia after splenectomy.

Pearce[17] and his co-workers in Philadelphia have studied experimentally in animals the relation of the spleen to blood destruction and regeneration and to hemolytic jaundice. They have found that the increased resistance of the red blood corpuscles characteristic of splenectomized animals persists for a least a year. There is also a decreased tendency to jaundice after the administration of hemolytic sera.

It seems to be the tendency to support the general supposition that these diseases called clinically "splenic anaemia," "family jaundice" and "Banti's disease," are all primary blood diseases but apparently with the active hemolytic agent in the spleen. The number of cures reported after splenectomy in these various conditions is too great to allow any other assumption than that the abnormal process is situated in the spleen.

Gibson's[18] recent report on the possible infectious etiology of certain of these conditions is of particular interest. Gibson finds that "in the spleens of six cases, three with the picture

of Banti's disease, two with splenic enlargement and fibrosis and one with splenomegaly there was found by a special method of staining an appearance which can be interpreted only as a parasitic invasion of the organ by a streptothrix organism this being in such a relation to the affected parts, at least in the cases of Banti's disease as to leave no doubt that they are the cause of pathological conditions. Many other spleens examined with the same object in view showed no such appearances." Gibson's work of course points to the infectious nature of certain cases of splenomegaly and Banti's disease. This work naturally awaits confirmation.

Leukaemia. The conflict is still waged concerning the classification of the various forms of leukaemia. Herxheimer[19] in a comprehensive article with an excellent bibliography gives an admirable review of the classification of leukaemia. By means of the so-called oxydase reaction, which is positive in all cells of the myelocyte series and negative in all cells of the lymphocyte series, an adequate means of differentiation seems to have been obtained. Herxheimer reports typical cases of the so-called lymphatic leukaemia and myelogenous leukemia and gives illustrative cases also of leukaemias with cells much less differentiated than the typical lymphocyte and the typical myelocyte which are classified as lymphoblasten-leukaemia and myelo-blasten-leukaemia. He reports one case which seems to have been a true mixed type in one person. The evidence is slowly accumulating that acute myelogenous leukaemia once considered rare is relatively common. Burgess[20] in his study of leukaemia using the oxydase reaction believes that acute leukaemia is usually myelogenous.

Steele[21] reports the finding of a diphtheroid bacillus in a gland from a case of lymphatic leukemia, apparently identical with that found by himself, Negri and Miermet,[22] Bunting and Yates, Billings and Rosenow in Hodgkin's disease. The well known wide distribution of diphtheroid bacilli renders further confirmation of this finding in lymphatic leukaemia as well as in Hodgkin's disease very essential.

The therapeutics of leukemia can be classified under three groups, x-ray, radium preparations and benzol.

X-Ray in Leukaemia. It has been well established that x-ray treatment improves the blood picture and the symptoms and favorably modifies the course of certain cases of chronic leukaemia. Béclère and Béclère[23] report the results of the x-ray treatment of 110 cases of leukaemia since June, 1904. Their 12 cases of lymphatic leukaemia, one of which has been observed for five years, were all improved. Their 93 cases of myelogenous leukaemia were much less favorably affected. There was no effect in the five acute cases. Cumberbatch[26] reports a fatal leukopenia following 111 days of x-ray treatment of a case of myelogenous leukaemia. The white count fell from 691,000 to 850. The differential count was not essentially altered. Warthin[27] studied the minute changes produced in leukaemic tissues by exposure to the Roentgen rays. In none of his cases were the conditions of the haematopoietic organs changed to normal. The effect of the treatment was degenerative and inhibitive but not curative as the essential process seemed to progress unchecked.

Radium in Leukaemia. As in the case of pernicious anaemia extravagant claims have been made for the therapeutic value of radium and its preparations in all forms of leukaemia. Thorium-x has been the preparation usually employed. Rosenow[28] in a critical review concludes that thorium-x has not been of the value in the treatment of leukaemia that it was once considered. Thorium-x often benefits but accomplishes no more than the x-ray and often fails. Meseth[17] reports improvement in three cases of myelogenous leukaemia and apparent cure in one case. Thorium-x was unsuccessful in cases of lymphatic leukaemia. Klemperer and Hirschfeld[29] review the present state of the thorium-x treatment. It is not possible to summarize the extensive and conflicting literature on the subject. It would seem fair to state that certain radium preparations, particularly thorium-x, favorably influence the blood picture and symptoms of certain cases of leukaemia. Cure apparently does not follow or at least is very rare.

Benzol in Leukaemia. v. Koranyi[30] in 1912 first used benzol as a therapeutic agent in leukaemia. He based the justification of his use on some clinical and experimental studies of Selling[31] of Baltimore who in 1910 reported three cases of benzol poisoning with blood destruction. Selling also showed the destructive effect of benzol on the blood in experimental work on animals. Other experimental evidence of the effect of benzol on the blood picture has been reported by Santesson[32] in 1897 and others. v. Koranyi and his assistant Királyfi[33] showed that the administration of daily doses of three to four g. of benzol, preferably given with equal parts of olive oil in capsules had usually a remarkable effect on the blood picture and symptoms in chronic leukaemia. After an initial rise in the white count, diminution in the white count begins after two or three weeks. This diminution is at first slow and then rapid. The red corpusceles are at first stationary but usually increase. The spleen and the glands become smaller. Patients who have had previous x-ray treatment seem to do better. v. Koranyi and Királyfi insist on the necessity of large doses. Gastro-intestinal irritation occurs in some cases. The treatment must be carefully controlled by the blood examination as leukopenia may be accompanied by general blood destruction and death. Since these initial reports, many cases of leukaemia treated with benzol have appeared in the literature. The

large majority of these cases were favorably influenced by benzol. A few cures are claimed. In this country Billings[34] of Chicago and Barker and Gibbes[35] of Baltimore have reported series of cases. v. Boltenstern[36] has recently reviewed the literature to date and gives 38 of the more important references. His conclusions are sound. He believes that benzol improves cases of leukaemia symptomatically, reduces the high white count but without curing the disease. He believes that at this early date no conclusive judgment can be passed on the value of this form of therapy. Several observers while reporting great improvement and reduction to normal of the white count have emphasized the striking fact that in the favorable cases with low white counts after benzol treatment the proportion of leucocytes are but little altered. The disease is still manifest by the relative increase of the abnormal blood constituents. Fatal cases after treatment with benzol have been reported by Neumann,[37] Jespersen,[38] Mühlmann,[39] Sohn[40] and others. In Neumann's case of myelogenous leukaemia the leucocytes fell from 56,000 to 200 before death. Jespersen and Mühlmann both report cases which relapsed and died after apparent cure. The autopsy of these fatal cases showed uniformly the extensive liver necrosis that is also found in animals experimentally poisoned by benzol. Sohn and Billings refer to the fact that with the reduction of the white count there is no coincident increase in the uric acid excretion. Sohn studied carefully the metabolism of a case of myelogenous leukaemia treated with benzol and found no increased uric acid output. This finding is difficult to explain on the assumption that benzol destroys the myelocytes. His interpretation is that there is a leukopenia in the cirulating blood and a hyperleucocytosis in the internal organs. It seems generally agreed that the acute cases are not affected by benzol. Krokiewicz[41] and others report cases of leukaemia entirely unaffected by benzol.

The present status of the problem would seem to be that cases of chronic leukaemia can often be favorably affected in regard to their symptoms and blood pictures by the Roentgen ray, by radium preparations and by benzol. The administration of all these therapeutic measures if pushed may result fatally. Leukopenia is to be avoided. Probably none of these measures really cure the disease. Benzol which is given by mouth has the great advantage of simplicity of administration. The results of benzol treatment appear to be more rapid, and more striking. The dangers would also seem to be greater.

Book Reviews.

Essentials of Bacteriology. By M. V. Ball, M.D. Seventh edition, thoroughly revised. With 118 illustrations, some in colors. Philadelphia and London: W. B. Saunders Company. 1913.

The first edition of this manual (No. 20 in the series of Saunders' Question Compendia) was reviewed in the issue of the Journal for Sept. 15, 1892 (Vol. cxxvii, p. 270). Since that time the first part of the book, on general bacteriology, has been considerably amplified. This seventh edition has been completely revised, and many chapters have been entirely rewritten. Those on immunity and infection have been edited by Dr. Paul G. Weston, who also contributed the article on the Wassermann reaction. There is at the end a very useful table of the chief characteristics of the principal bacteria. The book aims to be "a concise and systematic introduction to the study of bacteria and allied microörganisms," and seems now to fulfil this purpose as well as is practicable for a work of its size.

THE BOSTON

Medical and Surgical Journal

THURSDAY, APRIL 9, 1914.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States. $6.56 per year for all foreign countries belonging to the Postal Union.*

Papers for publication, and all other communications for the Editorial Department, should be sent to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston. All orders for reprints must be sent in writing to the Editor on or before the day of publication.

The Journal will furnish 100 reprints free, if requested in writing.

All letters containing business communications, or referring to the publication, subscription or advertising department of the Journal, should be addressed to the undersigned.

Remittances should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

THE GOVERNOR'S MESSAGE ON THE UNPAID BOARDS.

THE Governor's recent message, based on the report of the Commission on Economy and Efficiency as embodied in House Bill No. 2137, prescribes a radical change in the administrative system of dealing with the sick, the delinquent, and the poor in our state institutions. For many years Massachusetts has committed herself to the policy of unpaid boards of trustees in handling these problems. It is fair to presume that a part at least of the efficiency of these institutions, which has made the State a model for others all over the Union, is due to this system and to the class of men and women who have served willingly and without pay on these boards. To sweep away this entire fabric, which it has taken so many years to build up and which, while it doubtless can be improved in many ways, has shown its worth, and to replace it with a system almost revolutionary in nature, is a proposition which deserves the most serious consideration by the medical profession.

Briefly, the new plan as proposed by the Economy and Efficiency Commission, provides for the abolition of the State boards of charity and insanity, the prison commission, the four boards of parole, the commission on probation, the commission for the blind, and the boards of trustees of the following institutions: the four state sanatoria for consumptives, the eight state hospitals and asylums for the insane, the two schools for feeble-minded, the hospitals for epileptics, the hospital cottages for children, the two institutions for inebriates, the state infirmary and the state farm, the three state training schools for children, and the hospital school for crippled children. The inmates of all these institutions number about 22,000. The powers and duties of all these boards and commissions are to be vested in a single paid board of five. This board may appoint a "director of public institutions" who is to have immediate charge of the proper execution of the board's policies. This director, in turn, may appoint four executive secretaries to whom he may delegate such of his powers as he sees fit, as well as a business agent, who is to attend to the buying and distribution of supplies, etc. The bill also provides for the appointment by the Governor of boards of three visitors each, to the several institutions, who will have power to investigate, hear complaints, and to report.

This bill, as explained in detail in the report of the Commission on Economy and Efficiency, aims to remedy certain defects which are supposed to exist in the present system. Among such defects are: a conflict and multiplicity of duties at present assigned to superintendents, defects in methods of accounting, variation in cost per patient and number of patients per employee in institutions of the same class, and a lack of uniformity in organization of departments, business methods, and construction of buildings. Besides remedying these defects, the new system aims to bring about centralizing of authority, closer supervision of work actually done, and economy in obtaining supplies by means of a central purchasing agency.

While to a greater or less degree certain of the defects above mentioned may exist under our present system and should and doubtless will be remedied, there are certain very evident advantages which result from a system of unpaid boards which are not mentioned in the report of the Economy and Efficiency Commission, and which find no place in what they propose to substitute.

Chief among the merits of our present arrangement is the high class of men and women who give their services to the state—men and women, many of whom are experts in their line, and who from disinterested motives and with the one aim to render service to the state, are spending tremendous amounts of time, energy, thought, and labor to this end. To do away with

all this, to annul the personal and humanitarian side of such service, would be a foolhardy and dangerous step. To replace such a system by one which has not proved its worth or stood the test of time and which opens the way for political influences of any kind would be still worse. During the last five years of his life, the late Dr. Arthur Tracy Cabot gave willingly and freely from the deep store of his wisdom and experience, practically all of his time and energy for the cause of stamping out tuberculosis and aiding consumptives in this state. Massachusetts can ill afford to discard one system and inaugurate another which will permanently deprive the state of such services as these.

GROWTH AND NEEDS OF DISPENSARY WORK.

A REMARKABLE development of dispensary service in this country is attested by the Report just issued by the United States Census Bureau. Five hundred and seventy-four dispensaries and out-patient departments are recorded in this publication, representing an increase of 370%, as compared with the 156 dispensaries which were listed* in a similar report issued by the same Bureau in 1904. The number of dispensary patients treated in 1910 is said to be 2,440,018, a figure which is undoubtedly too low, but even this is 50% above the number recorded six years before. The census list of dispensaries omits, for some reason, several institutions of importance, among which the large out-patient department of the Boston City Hospital may be mentioned. It is probable that during 1913 at least 3,000,000 persons received treatment at dispensaries in this country, excluding the commercial dispensaries.

In 1904 the hospitals received 87 patients per 100,000 population of the United States, and in 1910 the proportion per 100,000 had risen to 107, an increase of 23%. Dispensaries and out-patient departments have grown much faster than hospitals, the number of which, between 1904 and 1910, increased only 28%, and the proportion of hospital patients per 100,000 population increased 23%. Dispensary patients per 100,000 population, however, increased from 1982, in 1904, to 2711 in 1910, or 36%.

* The 1904 figures are probably too low, 200 being a more likely figure. This would make the increase, in 1910, 287%.

The following classification suggests some of the varied causes of this rapid growth:

General dispensaries receiving more than 1000 patients a year	291
General dispensaries receiving less than 1000 patients a year	62
Dispensaries for tuberculosis only	167
Other dispensaries for special diseases (eye, ear, nose and throat, gynecological, etc.)	53
Dispensaries not in operation in 1910	1
Total dispensaries in the United States in 1910	574

It will be seen that 167 dispensaries have been established as part of the anti-tuberculosis campaign, and about nine-tenths of these began work between 1904 and 1910, the larger number in Pennsylvania under a state law. But the tuberculosis dispensaries do not account for more than a fraction of the growth between 1904 and 1910. The general dispensaries of the larger type increased during that period more than 200%.

The distribution of the dispensaries is very interesting. Seventy-nine per cent. of the total number of patients treated were in New York, Pennsylvania, Massachusetts and Illinois, and 10% more were in the four additional states of Maryland, New Jersey, Ohio and Missouri. Thus, 89% of the two and a half million patients recorded for 1910 were in 8 of the 48 states. On the other hand, the dispensaries are widely scattered, there being only 8 states in which there are no dispensaries. (In 1904, 27 states had no dispensaries.) While dispensaries have blossomed most freely in the largest cities, such as New York, Philadelphia, Boston, Chicago, Baltimore, Cleveland and St. Louis, their establishment in communities of moderate size is one of the striking features shown by the Census Report.

Other interesting items appear from a study of the expenses. The amount appropriated for dispensary work from public treasuries, mostly municipal, was $23,501 during 1904, and $217,192, or nearly ten times as much, during 1910. While many inaccuracies might be pointed out in the report of the Census Bureau, the larger part are evidently due not so much to inefficiency in Uncle Sam's service as to the inability of dispensaries and out-patient departments of hospitals to furnish the information desired. Nearly two-thirds of the institutions treating 1,000 or more patients a year do not make a financial report showing the expen-

ditures of the dispensary or out-patient department. Most hospitals do not keep their accounts so that the expenses of the out-patient department can be stated separately. This is true even of some of the leading institutions of the country. Only 191 dispensaries reported their expenses for 1910, the total being $1,593,140, a surprising figure in view of the fact that most of the large out-patient departments do not report.

There can be no doubt that dispensary service meets a real demand, which has thus far been manifested chiefly in the larger centres of population. The lack of adequate medical service in many middle-sized industrial communities which have little in the way of hospital provision, and few of the specialists demanded by modern medicine, is coming more and more to the attention of those interested in public health. In such communities, the establishment of dispensaries is beginning. Probably no section of medical work today, in institutions, varies so widely in quality as dispensary service. In too many cases the dispensary or out-patient department has been a feeder, a poor relation, of the hospital, not a clinic in which serious medical work is attempted with the average patient. That the dispensary has a place of its own as a great factor in treating and preventing disease among large sections of the population, is forcing itself upon the minds of medical men and hospital administrators. The appointment by the American Hospital Association, at its convention last autumn in this city, of a Committee on Standards of Out-Patient Work, is a witness of this recognition. Dispensary work has evidently become too large a factor in medical service in this country not to require levelling up, standardization, and progressive development in efficiency.

THE INTERNAL USE OF COCAINE.

IT is remarkable that, with the general properties of erythroxylon coca known for centuries, its most valuable alkaloid, cocaine, which was first isolated in 1859, by Niemann, should have been employed to so small an extent in internal medicine. There are, however, some circumstances which account in part for this. A survey of the literature upon the subject will show an abundance of very contradictory evidence regarding coca and its alkaloids, especially cocaine. In the use of preparations made from the crude plant itself these discrepancies can easily be accounted for, owing to the varying alkaloids contained in coca, some of which are highly toxic; also to possible variations in the strength and composition of preparations, since much of this work was done before the era of standardization of drugs. With a chemically pure cocaine there should not be such wide variations, though unless the cocaine is chemically pure, it may contain a certain amount of two very toxic alkaloids, one of which, isatrophycocaine, is a decided heart-muscle poison. Again, ever since the discovery of the anesthetic properties of cocaine the local uses of the drug have attracted such universal attention that the possibilities of its internal employment have been much neglected.

There can be little question that the latter deserves to be resorted to to a far greater extent than is now the case, and an able argument for such use is made in a paper on "The Value of Cocaine in Disturbances of Metabolism," which was read at a recent meeting of the Medical Association of the Greater City of New York, by Dr. William H. Porter, for many years professor of pathology and general medicine in the Post-Graduate Medical School and Hospital. This communication may be regarded as authoritative from the fact that Professor Porter has used cocaine internally for nearly thirty years and in many hundred cases, both acute and chronic. Both historic and experimental evidence, he says, seems to prove conclusively that this substance has the power to augment forcefully almost all the physiological activities of the animal economy and to sustain these augmented functions for a considerable period of time, thus materially enhancing the working power of the system. In physiological dose it stimulates in succession the cerebral hemispheres, the medulla, and the cord. Both mental and muscular activity are augmented to a certain extent, the respirations are increased, and the muscular contraction of the heart is slightly quickened and also increased in force. A slight rise in blood-pressure is caused, and the augmentation of both the respiratory and circulatory activity enhances the reduction processes of the body, an essential requisite in defective metabolism. It stimulates intestinal peristalsis and tends to improve digestion and the absorption of food, while glandular activity in general is more or less increased. It appears to excite all the functions of the body more uniformly

than any other known alkaloid. So long as the dose is kept within the physiological limit, only good will result, but beyond this limit, as in the case of other similar agents, bad results must follow, since it then depresses or arrests the physiological activities at first augmented. That there is a wide difference between its peripheral reflex stimulation and its oxidation reduction within the body is shown by the fact that patients who are profoundly depressed by cocaine when applied locally can take one and two grains of it internally three times a day, not only with no untoward effects, but with highly beneficial results. From the observation of several instances of this kind Porter has concluded that the local and the internal effects of the alkaloid are entirely different, and must be studied separately

In various disease processes and profound disturbances of metabolism in which the normal foods were no longer capable of exciting into physiological activity the sluggish protoplasmic masses of the economy, when everything was at a standstill, as it were, or when it became apparent that the patient was steadily losing ground, he has found, in a large number of cases during the past twenty-five years, that the use of half a grain or more of cocaine three times daily has produced almost miraculous changes for the better, even in those which seemed almost hopeless. In all chronic affections its power for good, he thinks, can hardly be overestimated. For the last ten years he has employed it more and more in the acuter diseases. When cocaine is given early in pneumonia, and throughout the attack, the results have convinced him that the chances for recovery are greater than without its administration. The same may be said of other acute affections, for if it has the great sustaining power which all the evidence seems to show that it possesses, the ability to eliminate the toxins of disease must be markedly augmented by it. It is a point worthy of special note that although he has prescribed this drug so extensively for nearly thirty years, he has yet to meet the first instance in which a patient has acquired the cocaine habit as a result of its internal use. Dr. Porter is accustomed to giving cocaine in capsules, and usually in combination with caffeine and strychnine. Should the criticism be made that one cannot judge accurately as to the true value of a remedy when it is given in conjunction with others, he would refer to the fact that he has sometimes found cocaine efficient in cases where all other means had failed This, to his mind, is the highest test for any remedial agent The discriminating mixture of several alkaloids, by the scientific physician, who knows the exact chemical composition of each, and just what each can accomplish alone and in combination, he believes to be a decided advantage

MASSACHUSETTS CONFERENCE ON TUBERCULOSIS. MASSACHUSETTS ANTI-TUBERCULOSIS LEAGUE.

The sixth session of the Massachusetts Conference on Tuberculosis was held in Boston on March 26, under the presidency of Dr. Walter C. Bailey, chairman of the trustees of hospitals for consumptives. All interested in the movement against tuberculosis were invited to attend and engage in the discussions, and there were many representatives from hospitals, sanatoria, boards of health, tuberculosis and nursing associations, and other organizations interested in health matters in all sections of Massachusetts.

In the forenoon the addresses were by Dr. P. Challis Bartlett, formerly superintendent of the Rutland State Sanatorium, on "Some Present Problems"; by Dr. Cleaveland Floyd, of Boston, on "Tuberculous Infection of Children"; and by Dr. Carl MacCorison, superintendent of the North Reading State Sanatorium, on "The Rôle of Family Clusters in the Prevalence of Consumption." Dr. MacCorison's study of family infection was based on the 1300 cases admitted to his sanatorium during the 3½ years since its opening. Among these there were 134 distinct examples of the incidence of three or more cases of consumption in a single family. Of 9371 persons who died of tuberculosis in Paris in 1911, 2523 were in houses where other cases had occurred.

In the afternoon the addresses at the conference were by Dr. George B. Underwood, president of the Gardner Association for the Relief and Control of Tuberculosis, on "The Social Worker's Educational Influence in the Tuberculosis Campaign"; and by Mr. Seymour H. Stone, secretary of the Boston Association for the Relief and Control of Tuberculosis, on "The Field-Work of the Anti-Tuberculosis Association." Mr. Stone pointed out that the state

has a well-defined policy of combating tuberculosis by providing for early cases at the State sanatoria, and requiring municipalities to segregate advanced cases in local hospitals aided by state subsidy. Several of these papers will be published in an early issue of the JOURNAL.

At the close of the session, Dr. Vincent Y. Bowditch, of Boston, was elected president of the conference for the ensuing year. Following this, the delegates from the various anti-tuberculosis associations organized the Massachusetts Anti-Tuberculosis League, by the adoption of a constitution and by-laws, and the election of the following officers:—

Presidents: Vincent Y. Bowditch, M.D., Boston, ex-President National Association for the Study and Prevention of Tuberculosis; J. F. A. Adams, M.D., Pittsfield, President Anti-Tuberculosis Association; Walter P. Bowers, M.D., Clinton, President Anti-Tuberculosis Association, Pesident Massachusetts Medical Society; James C. Coffey, Worcester, Agent Board of Health.

Treasurer: Arthur Drinkwater, Cambridge, Trustee Massachusetts Hospitals for Consumptives.

Secretary: Seymour H. Stone, 4 Joy Street, Boston, Secretary Association for Relief and Control of Tuberculosis.

Executive Committee: Roger I. Lee, Chairman, Boston; Henry Abrahams, Boston, Cigar Makers' International Union; Vanderpoel Adriance, M. D., Williamstown, President Anti-Tuberculosis Association; Carl A. Allen, M.D., Holyoke, President Association for Prevention and Relief of Tuberculosis; Walter C. Bailey, M.D., Boston, Chairman Trustees Massachusetts Hospital for Consumptives; Enos H. Bigelow, M.D., Framingham; Herbert C. Clapp, M.D., Boston; Eugene A. Darling, M.D., Cambridge.

Already twenty-three anti-tuberculosis associations have joined the League for the purpose of working together in the fight to eradicate the disease. This is an important step and should help to coördinate the work throughout the state.

The office of the League will be at 4 Joy Street, Boston, and anyone interested in the problem can become a member by the payment of $1.00 per year. Anti-tuberculosis associations and other health organizations are eligible to membership.

MEDICAL NOTES.

AWARD TO DR. RICE.—Report from London on March 27 announces that the King's medal of the Royal Geographical Society has been awarded this year to Dr. Alexander Hamilton Rice of Boston, for his distinguished work in the exploration of the Amazon and Orinoco river basins.

TWO FOREIGN MEDICAL CONGRESSES.—The forty-third Congress of the German Surgical Society will be held in Berlin from April 15 to 18, inclusive.

The next congress of the International Association of Thalassotherapy will be held at Cannesvon, April 15 and following days, under the presidency of Professor d'Arsonval. Prince Albert I of Monaco, a member of the Institute of France, will be honorary president. The question which will be specially studied is heliotherapy, and the reports to be presented will deal with the nature of solar radiations at the sea level and the means of measuring them; marine heliotherapy in its relation to actinomometry and climatology, the biological effects and dosage of marine heliotherapy; its effects in surgical tuberculosis, in abdominal tuberculosis, in pleuro-pulmonary and adeno-mediastinal tuberculosis, in the treatment of cutaneous tuberculosis, and in tuberculous affections generally.

GIFTS BY AN AMERICAN PHYSICIAN.—Report from Berlin on March 28 announces that Dr. Joseph Schneider, of Milwaukee, Wis., who in 1912 gave $25,000 for the promotion of public health in his native city of Würzburg in Bavaria, has recently made another gift of $25,000 for the same purpose.

OPENING OF THE HOOPER INSTITUTE.—The Hooper Institute for Medical Research, at the University of California Hospital, San Francisco, was officially opened on March 7, with addresses by Dr. Henry S. Pritchett, of the Carnegie Foundation, and Dr. Richard Mills Pearce of Philadelphia. The institute was founded with an endowment of $1,000,000 in memory of Mr. George William Hooper by his widow.

NEW DEPARTMENT OF ROCKEFELLER INSTITUTE.—On March 31, the New Jersey state legislature passed a bill permitting outside medical societies to engage in animal experimentation within the state. This was done to enable the

location at Rahway, N. J., near the New Jersey Agricultural Experiment Station, of the new department of the Rockefeller Institute for the study of animal diseases, for the endowment of which Mr. John D. Rockefeller has recently given a fund of $1,000,000.

BOSTON AND NEW ENGLAND.

Lectures by Dr. Fischer.—Dr. Guido Fischer, of Marburg, Germany, has been in Boston the past fortnight, giving at the Harvard Dental School a series of clinical lectures to show his methods of local dental anesthesia.

Danvers State Hospital.—The recently published thirty-sixth annual report of the trustees of the Danvers (Mass.) State Hospital records the work of that institution for the year ended Nov. 30, 1913. During this period the total number of patients treated was 2216, of whom 1029 were men and 1187 women. There were 206 deaths, in 86 of which cases autopsies were performed. From the training school, 7 nurses were graduated. Attention is called to the urgent need of a nurses' home for male attendants and married couples.

Boston Lying-in Hospital.—The recently published eighty-first annual report of the Boston Lying-in Hospital records the work of that institution for the calendar year 1913. During this period 884 babies were born in the hospital and 1824 in its out-patient department. Thirty-six nurses were graduated from the training-school. Particular attention should be called to the work of the pregnancy clinic, which during the year had supervision of 1652 prospective mothers. The value of this work in the prevention of pathologic complications and in public education is of great moment.

Massachusetts General and McLean Hospitals.—The recently published one hundredth annual report of the trustees of the Massachusetts General Hospital records the work of that institution for the calendar year 1913, the second year of the second century of its existence. With it is published the ninety-sixth annual report of the superintendent of the McLean Hospital. During this year 6251 patients were admitted to the wards of the General Hospital, 5424 were treated in the accident room, and 24,887 new cases in the out-patient department. The new Nurses' Home was opened during the year, and 46 nurses graduated from the training-school. A similar new home is needed for nurses at the McLean Hospital. At this hospital 364 patients were under treatment during the year; while 733 were received at the Convalescent Hospital in Waverly. The urgent needs of the General Hospital are an administration building, a private ward, and a ward for children. It is earnestly to be hoped that the charitable generosity of the public, of which there has already been abundant evidence, will soon make possible these necessary additions to the equipment of the hospital for further service and progress.

NEW YORK.

Division of Child Hygiene.—Dr. H. L. K. Shaw, director of the Division of Child Hygiene, of the State Health Department, established by the new health law, announces his plans in the *Bulletin* of the department. Among the matters included in these are the establishment of infant milk or welfare stations, the encouragement and systematizing of prenatal work, and local campaigns for the reduction of infant mortality, assisted by the department by means of exhibits, literature and lectures. The division is prepared, he states, to coöperate actively with local officials and others, so that the toll of infant lives this year may be appreciably lessened.

Apropos of the recent appeal of the New York State Grange for a Division of Rural Hygiene in the State Department of Health, the department has announced its readiness to do its part, and Commissioner Biggs expresses the opinion that with sufficient funds to establish and maintain an active and efficient division of the kind, there is no reason why the Health Department cannot save thousands of lives which are lost each year by preventable diseases.

New York Milk Committee.—The New York Milk Committee, through its secretary, Paul E. Taylor, secretary of the New York Milk Committee, has issued a statement in which he asserts that since 1907 more than $2,000,000 has been wasted by the state of New York through indemnity granted to what appears to be the selected list of owners of tuberculous cows. Many of the condemned cows, he says, have been milked until they became dry, and then fattened for food purposes after installations in state institutions. The health of boys who are inmates of these institutions has been endangered

through caring for the tuberculous cows. New York pays from $75 to $125 each for the diseased animals, while the standard price in New Jersey is $15. It is furthermore charged that New Jersey farmers sell the diseased cattle to sausage factories in Jersey City, and that their meat is made into bologna sausages and sold in New York.

PREVENTION OF TUBERCULOSIS.—The committee on the prevention of tuberculosis of the Charity Organization Society has issued a report covering the last three years. In it reference is made to the greatly overcrowded condition of the tuberculosis hospitals of the city. At the large Metropolitan Hospital on Blackwell's Island there have at times been more than 36% more patients than it was designed to accommodate normally, and the same state of affairs has existed to a greater or less degree in all the institutions of the kind. The hospital authorities are not to blame as, under the law, they cannot refuse to admit patients; nor are the financial authorities censured. The latter have been extremely generous, but it seems to have been impossible to keep up with the city's needs. At present, however, the situation is somewhat relieved. An appropriation of $2,000,000 has been made which will soon increase the number of hospital beds available for tuberculosis patients from 2270 to approximately 4000. This provides for the completion of Sea View Hospital, on Staten Island, which will accommodate 1000 patients, for the addition of a new pavilion accommodating 112 at the Metropolitan Hospital, for two additional pavilions at Riverside Hospital, on North Brother Island, and for new pavilions and shacks at the Otisville Sanatorium. The outlook is considered encouraging, as the official reports of the Health Department show that the death-rate from pulmonary tuberculosis in the city has fallen from 2.25 in 1908 to 1.66 in 1912.

APPOINTMENT OF DR. EMERSON.—At a meeting of the City Board of Health, held on March 31, Dr. Haven Emerson, associate in physiology and in medicine at Columbia University and assisting visiting physician to Bellevue Hospital, was appointed sanitary superintendent and deputy commisioner of health.

POLLUTION OF BATHS.—Health Commissioner Goldwater has sent a letter to Borough President Marks in which he states that his department will issue no permits this season for either public or private baths in Manhattan waters, as tests have conclusively shown that the waters of the Hudson, Harlem, East River, and Upper Bay are dangerously polluted with sewage. He expresses the opinion that many cases of typhoid fever and other diseases have been due to bathing in these waters. That the poor may not suffer from this deprivation he urges that increased facilities for interior bathing should be provided by the city at the earliest possible date.

RECEPTION TO DR. L'ESPÉRANCE.—A farewell reception was given Dr. Elise S. L'Espérance, this year's winner of the Mary Putnam Jacobi Fellowship, on the afternoon of April 4, at the residence of Dr. Emily Dunning Barringer, 828 West End Avenue, New York City. All women physicians were invited to meet both Dr. L'Espérance and also Dr. Alice Rohdè, the first winner of the fellowship. The Mary Putnam Jacobi Fellowship Fund was raised through the efforts of the members of the Women's Medical Association of New York City, many of whom had been pupils of Dr. Jacobi at the Women's Medical College of the New York Infirmary. It is open to all women graduates in medicine. Dr. L'Espérance sails in April to continue her cancer research work, which she is pursuing under the direction of Dr. Ewing of Cornell.

1. McCaskey says that functional impairment of the kidneys may be limited to certain classes of waste products. There may be varying degrees of renal block for urea, chlorides and water, and from a therapeutic point of view it is of the greatest importance

to differentiate between these types because dietetic treatment depends upon it. The phenolsulphonephthalein test is inadequate because there is no parallelism between excretion of phthalein and of urea. By surcharging the blood with urea and determining the rate of its excretion, the permeability of the kidneys for this substance can be determined with great accuracy. Unless there is gastric stasis the ingestion of 30 grams of urea is sufficient. The capacity of the kidneys for the excretion of chlorides and of water can be determined in the same way but the problem is more complex. [L. D. C.]

1. Anderson makes out a strong case against the use of crotalin (rattlesnake venom) in any diseased condition in which it is used entirely empirically, such as in epilepsy and tuberculosis.

2. Experiments by these authors furnish evidence that fat administered to animals and presumably stored in part in the liver increases the susceptibility of the organ to the injurious action of chloroform. In view of the well-known solubility and diffusibility of chloroform in fats, they suggest that the fat of the liver cells determines the fixation of chloroform and occurrence of necrosis. The experiments with carbohydrates, on the contrary, furnish confirmation of the views that carbohydrates protect the body proteins from disintegration. Since necrosis of the liver with a variety of diseases, namely, toxemia of pregnancy, acute yellow atrophy of the liver, yellow liver and poisoning with a variety of substances exhibits close similarity to the necrosis of chloroform, it is suggested that a carbohydrate diet may be found to influence favorably the course of these diseases. [E. H. R.]

3. Vest records some unusual symptoms following the use of collargol in pyelography in six cases. Ten and fifteen per cent. solutions were used. Severe pain may result, with rise of temperature up to 102°, with definite urinary changes. He advises against using collargol for such purposes unless absolutely necessary. If used it should be allowed to enter the renal pelvis very slowly and under very slight pressure. [J. B. H.]

9. *FLOYD AND WOLBACH. *On the Differentiation of Streptococci; Preliminary Notes.*

9. Floyd and Wolbach present the preliminary report on the work of differentiation of streptococci. As a rule those organisms presenting high virulence

show slight fermentative properties. It is evident that, in all probability, not so many groups of this variety exist as was believed by Winslow. The gentian violet test for virulence may be of rough value, though it is of no great value. Further work is suggested along the line of agglutination and complement fixation. The latter test may prove of great value in differentiation. At present the greatest dependence is placed upon the sugar-fermentation reaction and the virulence of the organisms to laboratory animals. [L. H. S.]

1. Brewer in animal experimentation finds that an aluminum band will produce a mechanical closure of the pylorus in every instance, that in every experiment in which the animal lived more than nine days the band was completely embedded in newly formed tissue and invisible, and that in none of the animals did the band give rise to necrosis of the compressed tissues, signs of irritation or leakage.

3. McWilliams' article is of extreme value and practical importance. He finds that if the whole diameter of a bone be removed, then this bone will regenerate between the ends of the fragments if the whole or a part of the periosteum be preserved, binding the defect, but very little filling in will take place if the entire periosteum has been removed from between the fragments. Provided a graft be living and taken from the same patient, its future life depends on an efficient blood supply, irrespective of whether it is in contact with living bone or periosteum or not. Periosteum when transplanted alone into soft parts may produce living bone. Splitting of the periosteum of a graft is unnecessary. No matter what the blood supply, grafts should be transplanted with as much periosteum as possible.

4. Elsberg in an excellent paper containing many excellent illustrations, describes his method of extension in the surgical treatment of intramedullary affections of the cord. The method is as follows: The laminectomy being done and the dura opened, a short incision is made over the area where the growth seems nearest the surface, dividing the pia and substance of the column down to the tumor. The tumor will then begin to bulge through the incision. It should never be excised then but the wound loosely closed and reopened at a second operation a week or ten days later, when the tumor will generally be found to have extended itself and can be easily separated from adhesions and removed. Eleven illustrative cases are published in the article.

5. McGlinn does not believe that the definite entity of fibroid heart exists. Arteriosclerosis in these tumors is a part of the advanced age and not directly referable to fibroids.

6. The authors claim that the phthalein test affords an indispensable index of the true renal condition in functional impairment due to obstruction in the lower urinary tract.

9. Cole produces some truly beautiful skiagraphs of gall-stones and emphasizes the importance of Roentgen examination to differentiate between right renal calculi and gall stones. [E. H. R.]

19. GARRETT, N. M. *Management of Labor in Cases with Relatively Contracted Pelves.*

1. This article describes by text and beautiful plates the technic of this operation. The authors believe this operation has certain advantages over

gastro-enterostomy and few of its disadvantages. The only contraindications are inability to mobilize the duodenum when adhesions are too dense and thickening and infiltration about the pylorus; also in gastric disturbances not dependent on organic disease. The special advantages lie in the opportunity to excise all ulcers in the anterior walls of the stomach or duodenum after direct inspection, also application of treatment to ulcers in the posterior walls. Immediate and final results are most encouraging.

2. This article is of interest and worth careful study, especially to those interested in carcinoma and its early diagnosis.

3. These authors believe that the end results for cancer of the breast are as good as, if not better, than the results for cancer elsewhere. Prognosis in young people who had the benefit of early operation was better than expected. Results are evidently improving and this seems due to the fact that patients are coming earlier to operation, rather than to any improvement in technic.

4. Mortality in gastric hemorrhage is becoming less, chiefly because of increasing accuracy of recognition of the proper type of case in which surgery is to be employed.

Articles 5, 8, 9, 12 and 13 are of especial interest of a practical sort, but not especially adapted to review. [E. H. R.]

The Lancet.

February 21, 1914.

6. Corbett, D. *A New Radiometer for Use with Sabouraud's Pastilles.*

1. In this second Hunterian Lecture Graves takes up the methods of transfixing bolts and bolted plates as useful in cases of para-articular fractures, fractures of the long bones, etc. He considers the various kinds of plates, and the use of intramedullary pegs. He discusses the treatment of old cases of non union, indirect fixation by transfixion apparatus, immobilization by splints or plastics, et al. He goes into the various methods of treatment by massage and early movement, and methods of extension. He discusses those cases suited for operative treatment, and compares operative and non-operative methods. There are numerous diagrams and illustrations.

2. In an article with an extensive bibliography, Spencer describes the thyreoglossal tract and the various abnormal conditions, cysts, etc., which may arise along its course. He presents numerous illustrative cases. [J. B. H.]

5. Whitfield, A. *On Three Cases of Eczematous Dermatitis Produced by Poisonous Plants.*
6. Maylard, A. E. *The Fate of a Plug of Iodoform Gauze Accidentally Left in the Abdomen.*

1. In the first Hunterian Lecture Gilford defines infantilism as a conspicuous arrest or delay of development, subdividing it into infantalism of cells, of organs, or of the individual as a whole. This latter he further subdivides into toxic and correlative infantilism. This somewhat complex subject he considers in great detail.

2. Sherman presents a mass of statistics, tables, and other information of the greatest importance in this article, which, however, is very difficult to review. As a summary of an immense amount of work, brought up to date (the paper was read Oct. 23, 1913, in Berlin) it is of immense value to all interested in this subject. Much of this first paper is devoted to general consideration and a discussion of the nature and modes of infection.

3. Fairlie concludes that ether is better for short operations without shock, but that chloroform is better for longer and more serious operations. [J. B. H.]

British Medical Journal.

7. Harrison, W. J. *Chronically Enlarged Tonsils and Their Treatment.*
8. Wilson, W. *Earache of Obscure Origin.*

1. The writers analyze 200 cases of appendicitis in children. Of the 60 acute cases, 3-13 years, 19 died, a mortality of 15%. There were no cases of either pneumonia or bronchitis in the entire series. He believes that in acute cases a resulting diffuse peritonitis is not uncommon; that prognosis in any given case is absolutely uncertain, and that complaint of abdominal pain, especially when accompanied by sickness should always provoke careful inquiry and examination. No aperients should be given by mouth or by any other route, and all food should be withheld.

5. Cantle describes the use of the tuning-fork-stethoscope method in outlining with precision such organs as liver, spleen, stomach, cecum, heart, etc. The tuning fork, when vibrating and placed over solid organs gives out a loud note; over hollow viscera, only a soft note to the person listening over this area with a stethoscope. This method is of interest and may be of value. [J. B. H.]

14. BILLING, E. *The Relation of the Time of Day to Mortality.*
15. DALAL, A. K. *Care of Rat-Bite Fever, Treated with Intravenous Injections of Neosalvarsan.*

1. In a long paper Lane again reviews the subject of chronic intestinal stasis and cites his own well-known views upon the surgical treatment of this condition. There are many illustrative diagrams. Both the conclusions which Lane draws as to the far-reaching effects of such stasis as the cause of apparently all the ills to which we are subject, and the ideas as to operating go much too far and too fast for the average American to keep pace with.

2. This is a highly technical article on a subject still in the experimental stage.

3. This paper is one of practical value to surgeons and general practitioners. There are numerous excellent plates.

6. Carliss in a long article discusses the diagnosis of various acute abdominal conditions due to hemorrhagic, inflammatory or obstructive lesions. [J. B. H.]

6. BONDI, J. *The Relation of Maternal Nutrition to the Weight of the Fetus.*

2. The author describes seven series of experimental inoculation of cancer in rats with a consideration of comparative rapidity of growth in gravid and non-gravid animals. In one case only was the tumor in the gravid as large as in the non-gravid; in one series there was no growth but resorption in the gravid animals. It would seem from this that pregnancy acts unfavorably to the growth of tumors. Ehrlich's theory of atreptic immunity may offer the explanation. The developing ovum may be considered a parasite as also is the malignant tumor, the one growing at the expense of the other. [F. S. K.]

10. A long, technical article with illustrations showing some excellent cosmetic results after Brophy's operation for hare lip.

11. Waljaschko and Lebedew suggest the use of a leaf of superficial fascia in closing wounds of the parenchymatous organs. The fascial covering acts as a hemostatic, and offers the suture-material a hold similar to that furnished by the capsule of an organ. Fewer sutures need be used, and the pressure need not be so great, thereby decreasing the amount of parenchymatous tissue which would otherwise be liable to pressure necrosis. Multiple rupture of the kidney has been treated in this way with good results, and the writers suggest the use of a leaf of fascia as a substitute for the kidney capsule.

13. Toida, experimenting with bile obtained from men and dogs, found that the bile of both is normally sterile. Human bile he found to be a very good medium for bacillus coli, fairly good for the bacilli of Asiatic cholera, bacillus paratyphosus B. and B. dysenteriae (Shiga-Kruse group), slightly favorable for bacillus pyocyaneus and staphylococcus pyogenes aureus. It was unfavorable to the streptococcus pyogenes and diplococcus pneumoniae. The

bile of dogs seemed a less suitable medium for bacillus coli, bact. paratyphi a., bact. dysenteriae Shiga-Kruse and staph. pyogenes aureus.

Human bile appeared to increase the virulence of Bac. Coli Communis, and in the incubator most of the organisms mentioned, except streptococcus and pneumococcus, lived for a month, some for 70 or 80 days. Age and sex seemed of little importance. [G. G. S.]

6. *LÖHE, H. *Experiments with a New Iodine-Albumin Preparation (Testijodyl).*
7. MEIDNER. *Modern Radium Treatment of Tumors.*

6. Löhe reports his experience with testijodyl, a new iodine-albumin compound, in the treatment of syphilis. His patients took the tablets without difficulty, and he observed no untoward effects. The acne and coryza often observed after iodide of potassium, were lacking. The specific action of the remedy, whether given alone or with mercury and salvarsan, was prompt and very similar to that of potassium iodide. The amount of iodine received by the patient is considerably less than in the usual dosage of the iodide. [L. D. C.]

5. CAZALBOU, L. *The Cultural Evolution of Dermatophytes.*

2. Cinca has studied experimentally the effect of a sterile abscess produced by turpentine upon the presence of trypanosomes in the blood and without the use of atoxyl. The abscess forms from the turpentine in about 4 to 5 days. In his first series he studied the effect of these abscesses upon the trypanosomes of Ouganda and Surra in the guinea-pigs. The appearance of the trypanosomes in the blood was retarded for some time, and after they had appeared such an abscess would make them disappear entirely or become greatly diminished for some time, but a recurrence of the parasites appeared later. The animals treated thus survived somewhat better than the controls. His second series was treated both by the turpentine abscess and atoxyl. The animals treated with both showed a more marked disappearance of the parasites from the blood than those treated only with atoxyl. After the abscess repeated injections of atoxyl would keep the parasites from the blood for a long time but could not produce a permanent cure. He feels that the abscess and atoxyl treatment combined is more satisfactory than either treatment alone and thinks it may prove of considerable value in the treatment of animals for these infections. [C. F., JR.]

4. BONAZZI, O. *Some Observations on the Etiology of Parotitis.*

3. In the *Journal of Urology* for January, 1913, Nicolich and Marion published each a case of fatal air embolism following inflation of the bladder prior to suprapubic prostatectomy. To determine the route by which the air could have entered the circulation, Santini performed twelve experiments on dogs, which he reports and from which he derives the following conclusions:—

(*a*) A healthy bladder will burst from high pressure before injected air will enter the ureters.

(*b*) To force air into the ureters it is necessary to injure the muscular fibres which reinforce the posterior wall of the ureter in its intravesical course.

(*c*) By injecting air directly into the ureters it is possible to make it enter the renal parenchyma so as to produce gas embolism.

(*d*) The air traverses the collecting tubules and the absorption zone between the medulla and the cortex.

(*e*) A minimal pressure, however, is sufficient to force the air through a vesical vein into the inferior cava and right heart.

(*f*) In gas embolism from insufflation, therefore, the route is probably through veins opened by lacerations of the mucosa. [R. M. G.]

2. Scalone describes in detail the technic of his method of producing permanent stenosis of large vessels in the treatment of aneurysm. This description should be read in the original, as it cannot well be abbreviated for abstract. It seems to be a contribution of genuine value to vascular surgery. [R. M. G.]

Obituary.

THOMAS MORGAN ROTCH, M. D.

IN the death of THOMAS MORGAN ROTCH, Professor of Pediatrics in the Harvard Medical School, March 9, 1914, the profession of medicine, Harvard University, and a large number of patients and personal friends, have sustained a grievous loss. Dr. Rotch, for many years the leading specialist in the diseases of children in New England, was born in Philadelphia on December 9, 1849. His father was Rodman Rotch of New Bedford, and his mother Helen Morgan of Philadelphia. His great-grandfather, Samuel Powel Griffiths, was a prominent physician in Philadelphia, holding the professorship of Materia Medica in the University of Pennsylvania from 1791 to 1796.

Dr. Rotch was graduated from Harvard College in 1870, and, having chosen medicine as a profession, entered the Harvard Medical School in the autumn of the same year. While in the school he took the first prize of the Boylston Medical Society. He was appointed one of the house physicians of the Massachusetts General Hospital in the autumn of 1873, and took his medical degree in 1874. Immediately after his graduation he went to Europe to complete his medical education. His studies were especially carried on in the universities of Berlin, Vienna, and Heidelberg, and after an absence of two years he returned to America, settled in Boston, and began his life's work in the practice of medicine.

At this time there was no physician in New England whose practice was especially devoted to children, and there was practically no teaching at Harvard in children's diseases. From the very beginning of his medical career Dr. Rotch evinced the greatest interest in and enthusiasm for the promotion of all knowledge pertaining to children. For the past thirty-eight years he labored unceasingly to increase this knowledge, and his investigations, writing, and teaching have given invaluable additions to this branch of medicine. His constant endeavor was to convince the American people that too little thought and practical attention have been given to the early years of life.

Dr. Rotch's principal life work was the building up in the Harvard Medical School of a department devoted to children. He was convinced that the anatomy, physiology, and pathology of early life differed so greatly from those of adult life, that special teaching of this subject was of the highest importance in medical education. His chief interest was in the organization and efficiency of the pediatric department of Harvard University. In 1888, the university established a chair for the diseases of children especially for Dr. Rotch. His title later was changed to Professor of Pediatrics.

For the past twenty years Professor Rotch was much interested in developing the work of the Infants' Hospital, the first hospital in this country to admit patients restricted to the first two years of life. Dr. Rotch always believed that babies should be cared for in a hospital entirely separate from children and from adults. In this hospital he elaborated one of the great works of his life, the system of percentage feeding, which has made his name well known in Europe as well as throughout America.

In 1902 Professor Rotch was invited to England to address the Children's Section of the British Medical Association on "The American

methods of modification of milk in the feeding of infants," presenting his pioneer work on this subject. This resulted in the establishment of a milk laboratory in London and in the adoption of the percentage method of feeding in England, especially in the London Infants' Hospital, of which at that time he was made consulting physician. Professor Rotch was senior physician of the Children's Hospital and of the Infants' Hospital, and was also medical director of the Infants' Hospital. He was consulting physician to the Boston City Hospital and physician emeritus to the Boston Dispensary.

He has held the positions of president of the Suffolk District Medical Society, president of the American Pediatric Society, president of the New England Pediatric Society, president of the Boylston Medical Society, and councillor of the Massachusetts Medical Society. He was also a member of the Association of American Physicians and of the American Medical Association.

After seventeen years devoted to the study of children and to teaching in the hospital wards and in the Medical School, Professor Rotch published the results of his investigations in a large illustrated work on the Diseases of Children which under the title of "Pediatrics" has since been used as a Harvard textbook. This book had a wide circulation and was accepted as a standard both in America and in England. Of late years Dr. Rotch did a good deal of work developing the use of the Roentgen ray in connection with children. As a result of this work in 1910 he published an illustrated book on "The Living Anatomy and Pathology of early Life as shown by the Roentgen Method." Dr. Rotch has covered in his writings the entire field of early life, always striving to keep before the public the truth that it is the study and practical scientific care of this period of life which produce the best results for good citizenship at a later period.

In 1874, Dr. Rotch married Helen Rotch, the daughter of William J. Rotch and Emily Morgan of New Bedford. They had one son, Thomas Morgan Rotch, Jr., born on May 21, 1878. Dr. Rotch's only son died on March 13, 1902, in less than a year after taking his A. B. degree from Harvard University. The Thomas Morgan Rotch, Jr., Memorial Building of the Infants' Hospital has just been completed and opened. A portion of the funds were contributed at the time of the young man's death by his friends and those of his parents. This hospital, which forms one of the group of buildings surrounding the Harvard Medical School and which is probably the most perfect infants' hospital building in the world, was the chief interest of Dr. Rotch's last years. It remains as a monument to his genius in the planning of details, and is designed not only to be a hospital perfectly adapted to the care of babies, but also to be an educational centre for students, physicians, and the laity in connection with everything pertaining to infants.

All those who came into contact with Dr. Rotch in his life work were impressed with the breadth of his views and his devotion to his profession. He made the teaching of Pediatrics a vital part of medical education. He possessed a remarkable power of carrying out his purposes even against opposition, and his purposes were always big purposes. He was a man of the most untiring energy and perseverance with remarkable genius for organization. His ideals were always high ideals and his aims were always large aims. He looked always far ahead, planning for the future.

EGBERT LE FEVRE, M.D.

Dr. Egbert Le Fevre of New York, dean of the faculty and professor of therapeutics and clinical medicine in the University and Bellevue Hospital Medical College, died on March 30 from scarlet fever, after an illness of only four days. Dr. Le Fevre was born at Raritan, N. J., on October 29, 1858, and his father, the Rev. James Le Fevre, who was one of the trustees of Rutgers College, is still living. He was graduated from Rutgers in 1880, and from the medical department of New York University in 1883, and in 1910 each of these institutions honored him, Rutgers conferring upon him the degree of ScD., and New York University that of LL.D. He served as interne at Bellevue Hospital, and three years after completing his service there was appointed clinical lecturer on the practice of medicine in the University medical school. When the Bellevue school was united with that of the University he was appointed to the professorship held up to the time of his death. He served successively as visiting physician to the City Hospital and Bellevue Hospital, and was made consulting physician to St. Joseph's Hospital for Consumptives and the Red Cross, Beth Israel, Nassau, Nyack, Mount Vernon, and North Hudson Hospitals. He was also the author of an excellent work on physical diagnosis. Dr. Le Fevre was not only highly esteemed on account of his professional attainments, but greatly beloved for his personal worth, and on the day that his death was announced eloquent tributes to his memory were paid in the chapel of the university by Chancellor Brown and by the chancellor emeritus, Dr. MacCracken.

Miscellany.

INTERNATIONAL SURGICAL ASSOCIATION.

The fourth congress of this Association will be held at the Hotel Astor in New York City lasting four days, beginning Monday, April 13,

1914. This is the first time that the congress has ever had a meeting outside of the city of Brussels, where the first one was held in 1905 and repeated every three years. The membership of the Association is limited to a certain number from each country. The membership in the United States is about one hundred. The president of the fourth congress is Professor Depage of Brussels, Professor Willems of Ghent is president of the international committee, and Dr. L. Mayer of Brussels is the general secretary. The local secretary is Dr. J. P. Hoguet, 40 East 41st Street, New York City, and the American committee is composed of Dr. Roswell Park (deceased) of Buffalo, Dr. L. L. McArthur of Chicago, Dr. C. L. Gibson of New York City, and Dr. R. H. Harte of Philadelphia. These last three, with the addition of Dr. Rudolf Matas of New Orleans and Dr. R. G. LeConte of Philadelphia constitute the committee designated to represent the American Surgical Association in making preparations for the entertainment of the foreign members.

The program is limited to the consideration of three main topics:—

1. "Gastric and Duodenal Ulcers." Introduced by papers by De Quervain of Basel, Hartmann of Paris, Lecone of Paris, Mayo of Rochester, Minn., Moynihan of Leeds, and Payr of Konigsberg.

2. "Grafts and Transplantations." Introduced by papers by Morestin of Paris, Villard of Lyons, Ullman of Vienna, Lexer of Jena, and Carrel of New York.

3. "Amputations." Introduced by papers by Witzel of Dusseldorf, Ceci of Pisa, Kusmik of Budapest, Binnie of Kansas City, Durand of Lyons, and Ranzi of Vienna.

After the close of the congress, Thursday, April 16, most of the foreign members will make a tour of other cities, the itinerary including Philadelphia, Baltimore, Washington, Chicago, Rochester, Minn., Montreal, and Boston. The foreign members have been invited also to attend the session of the American Surgical Association held in New York at the Hotel Astor April 9, 10, and 11, and many have signified their intention of arriving on the *Imperator*, due April 9.

MEETING ON CANCER.

THE American Society for the Control of Cancer announces a public meeting to be held on Friday evening, April 10, at 8.30 o'clock at the New York Academy of Medicine, 17 West 43rd Street. Final arrangements for a symposium on the nature and control of cancer have been made.

Dr. Clement Cleveland, vice-president of the Cancer Society, will act as chairman of the meeting, and the discussion will be opened by Dr. William H. Mayo, the eminent surgeon of Rochester, Minn., and president of the American Surgical Association, which will be in session in New York City during the week.

Frederick L. Hoffman, LL.D., statistician of the Prudential Insurance Company, who will shortly publish the most thorough statistical study of cancer which has yet been made in America, will present the latest evidence as to the prevalence of this disease in New York City, in the state, and in the country, and will discuss the possibility of controlling the death-rate by educating the public in regard to the symptoms and early recognition and treatment of cancer, as has been done with conspicuous success in Germany.

Professor Francis C. Wood, M.D., director of cancer research for the George Crocker Special Research Fund of Columbia University, will read a paper on "The Nature of Cancer and its Cure." Dr. Wood is in charge of the cancer research laboratory recently built by Columbia University at 116th Street and Amsterdam Avenue.

"The Control of Cancer from the point of view of the Cancer Commission of Harvard University," is the subject chosen by Dr. J. Collins Warren of Boston, professor emeritus of Harvard University, and chairman of the Harvard Cancer Commission. Notable improvements in the treatment of cancer, especially by means of radium, have recently been described in the annual report of the Harvard Commission and are in use under its direction at the Huntington Memorial Hospital of the Harvard Medical School. Dr. Warren is also a trustee of the American Society for the Control of Cancer.

The meeting will be open to the public without cards of admission and there will be no reserved seats.

Correspondence.

THE MASSACHUSETTS MEDICAL SOCIETY.

COMMITTEE ON STATE AND NATIONAL LEGISLATION.

BOSTON, April 3, 1914.

Mr. Editor: The following is the brief of the Committee of the Massachusetts Medical Society on State and National Legislation regarding the very important legislation that is proposed in the Report of the Commission of Economy and Efficiency. Every physician should inform himself regarding the proposed legislation and do what he can to interest his friends in the matter.

Very truly yours,

ARTHUR K. STONE, *Secretary.*

44 Fairfield St., Boston.

The Committee of the Massachusetts Medical Society on State and National Legislation wish to register with the Ways and Means Committee their emphatic protest against the conclusions of the State Commission of Efficiency and Economy in their recent report to the Governor.

The committee is sure that to abolish the Boards having in charge the varied interests of the State wards would be a calamity. The complex problem of

caring for the sick, the mentally defective, and the criminal, requires subdivision and specialization of effort to achieve good results. The committee believes that the long-standing policy of the State of Massachusetts to care for its wards by means of unpaid boards of trustees, who can devote their time and ability to the study of the immediate problem of their particular institution, is a wise one, and has resulted in Massachusetts being in the fore-front of the states in the general intelligent treatment of its philanthropic problems. No single commissioner or small group of men could control all of this vast and varied sociological activity to advantage. Individuals have accepted membership in these unpaid boards chiefly because of an original interest in the peculiar class of persons whom their special board serves. Most interested in the feeble-minded are less so in the blind; those caring especially for dependent infants are more indifferent to prisoners or sufferers from tuberculosis. By long service on their respective boards, many have obtained a high degree of *expert knowledge* which is bound to be of great use to their beneficiaries. To abandon all these benefits, and to put all sorts and conditions of state wards under one central bureau, is to lose enormously in the helpful efficiency of our state charities, even if there were a small saving in the amount of money expended, which our committee doubts would happen. The financial saving would have to be far larger than it is likely to be to counterbalance the dozen or more new, salaried officers whom the bill provides for. And we believe the way the money is spent,—in other words, the expert intelligence employed in its spending,—is quite as important as the mere question of the amount spent.

The committee is further of the opinion that the assumed economies which would be carried out under the proposed machinery would not materialize. Any large institution can probably purchase as cheaply, and, what is of as much importance, have what is adapted to its particular needs, as could a large central purchasing agency, with all the intricate machinery of management which would be necessary to insure honesty and provide for the rapid distribution of materials to the various institutions. This doubtless could be accomplished, but no group of five men paid the proposed salaries could develop such a plan as would work efficiently for a great state like Massachusetts. In addition, the wants of the institutions are so varied that it would doubtless occur that there would be great waste of materials which did not meet the exact requirements of the superintendents; and no mere purchasing agency could be convinced that the special requirements were necessary. Even in the matter of building, the needs of the institutions are so different that no absolute standard of construction is either possible or desirable.

The committee believes that much can be done in a helpful way to standardize methods of accounting, to suggest certain standard methods of building, heating, and ventilation, and to encourage and help overworked superintendents by giving them proper assistants to aid them in their work. It should be recognized that some men are specially good administrators, and consequently should be given specially good clinical assistants; others are specially good in devising plans for the improvement of the persons entrusted to their care, and such men should have specially good administrative assistants.

It must be remembered in any attempt to standardize our institutions, that this state work has been going on for half a century, and that it has not been possible to foretell because of the enormous increase in population, the great complexity of the problems arising from the rapid growth of the urban population. In some cases where seemingly wise plans for the development of the institutions have been made, these plans have not been accepted by the legislatures and make-shift plans have had to be substituted, which in the long run have entailed additional expense.

Wise, helpful, constructive criticism of the institutions will undoubtedly do much to make for general economy, but this committee is quite sure that the plan proposed is destructive in its nature and makes for neither efficiency nor economy.

REGISTRATION OF NURSES: A REJOINDER.

BOSTON, MASS., March 30, 1914.

Mr. Editor: We are all in accord with Dr. Cook's hope "that the physicians of Massachusetts will post themselves thoroughly as to the present tendencies in the registration of nurses," but some of us cannot endorse the implied criticism that the needs of the well-to-do as against the needs of all classes, inspires the motive actuating the effort in behalf of the measure under consideration.

An analysis of Dr. Cook's article, made up largely of six quotations, seems to show that his conceptions of the practical working of the proposed legislation, would be to endow the Board of Registration of Nurses with a power which might imperil the existence of some of the training schools for nurses, and thereby might curtail the education of a sufficient number of nurses to meet the requirements of the people. He intimates that the members of the Board of Registration of Nurses, might use this power in an arbitrary and unjust manner and, therefore, should not be given this weapon to be used in dealing with inferior schools. If his argument should be carried out, then no discretionary powers should be given to any public officials, and every board should have absolute standards to govern its actions, and be made to adhere rigidly to rules made by a Legislature composed largely of people who cannot intelligently deal with problems which individual members may not have studied.

The trend of modern effort seems to be to study all educational methods, and to eliminate the weak or poorly equipped schools, both because the product of the inferior school is undesirable, and also especially because the school which advertises to give a good training and does not do so, is a fraud. Those who have investigated this problem, know that many young men and women have been induced to spend money and years of the best part of their lives in attendance at institutions where the published promises have not been kept.

Does the objector to this legislation, want these frauds, some of which are medical schools and some of which are training schools for nurses, to continue? Does he want imperfectly trained nurses with low moral and professional standards, to be placed before the people of this state simply because the demand for nurses is not fully met?

Have not this eminent physician and his associates, enough influence to induce the Governor to take cognizance of any pernicious activity on the part of the Board of Registration of Nurses?

We all confidently hope that there will be developed a nursing scheme which will provide for the needs of everybody, but in the meantime, it does not seem possible that the proposed legislation, which is only one step in the process of evolution, will be any barrier to progress. Very truly yours,

W. P. BOWERS, M.D.

REGISTRATION OF NURSES: ANOTHER REJOINDER.

BOSTON, March 31, 1914.

Mr. Editor: At the risk of being tiresome I am impelled to reply to Dr. Cook's letter in the JOURNAL of March 26th.

The nurses who are working for House Bill No. 1186 will unite with Dr. Cook in earnestly requesting the physicians of Massachusetts to post themselves thoroughly as to the present tendencies in the registration of nurses.

The writer of one of the letters from which Dr. Cook quoted is Dr. Hornsby, Editor of the *Modern Hospital* and was superintendent of the Michael Reese Hospital in Chicago. Dr Hornsby very kindly sent me a copy of his letter to Dr. Cook so that the nurses might know just what his criticisms were of the law in Illinois, as well as the bill that is now pending in Boston. In regard to the Illinois law he writes the following—not quoted by Dr. Cook:

"You will note also Section 2, line 9, that the board has the right of inspection of hospitals, presumably for the purpose of seeing that the training of nurses is adequate. In most cases the law has worked out all right in this respect . . .", he then cites one instance quoted by Dr. Cook at the hearing in the State House, where the inspector did not use good judgment. He then goes on to say "but on the whole our board members have been extremely sensible and the law seems to be working out all right."

This testimony from a gentleman in Dr. Hornsby's position in Illinois seems to warrant some encouragement to those who are working in other states for similar legislation. He closes the discussion in his letter as follows:

"But I believe most of this controversy is academic rather than vital for immediate purposes, because we have in the leadership of the nursing profession a group of sane, intelligent women who are quite as anxious that proper conditions should prevail as the medical profession could be, or the public, or the administrators of hospitals, and it is my experience that even the most divergent views in this controversy about nursing are apparent rather than real. We are not all of us at exactly the same point in the road of progress and consequently we do not see things from exactly the same angle, but we are going in the same direction, are headed for the same goal and we are all using the same make of compass, so I don't think we are going to get very far apart."

"As a matter of fact, nursing ideals and the qualifications of our present day nurses have improved so vastly in the last few years, under the present leadership in that profession, that it seems to me the whole problem is in pretty safe hands"

I am

Faithfully yours,

SARA E. PARSONS. R.N.,
Superintendent of Nurses.

NOTICES.

MASSACHUSETTS GENERAL HOSPITAL: A surgical meeting open to the medical profession will be held at 8.15 p. m., on April 10th, in the lower ampitheatre of the Out-Patient Department. Entrance on either Blossom or Fruit streets.

Dr. Daniel F. Jones will present a "Report on the Surgical Treatment of Cancer of the Rectum since 1900."

SOCIETY NOTICES.

MIDDLESEX SOUTH DISTRICT MEDICAL SOCIETY.—The annual meeting of the Society will be held at the American House, Boston, on Wednesday, April 15, 1914, at 11.00 a.m. The annual oration will be delivered at 12.00 o'clock, noon, by Dr. Charles D. McCarthy of Malden. Subject: "Medicine and Social Evolution."

Dinner will be served at 1.00 p. m.

LYMAN S. HAPGOOD, *Secretary.*

APPOINTMENTS.

DR. WILLIAM E. CHENERY has been appointed Chief of the Nose and Throat Department of the Forsyth Dental Infirmary for Children.

The following gentlemen have received and accepted appointment to the staff of the Forsyth Dental Infirmary for Children:—

CONSULTING SURGEONS, Hugh Williams, M. D.; F. B. Lund, M. D.; Hugh Cabot, M. D.; H. H. Germain, M. D.

CONSULTING PHYSIOLOGIST, George Tarr Ney Dearborn, M. D., Ph. D.

CAPTAIN ARTHUR N. TASKER, Medical Corps, United States Army, has been selected as lecturer on tropical medicine at the Long Island College Hospital. This is a new chair recently established by the faculty of the school.

RECENT DEATHS.

DR. WALTER A. HAYNES, a dentist of Boston, died on March 28 at Revere, Mass. He had served for many years on the Revere board of health. He is survived by his widow.

DR. CHARLES EMERY ROWELL, who died on March 29 at Stamford, Conn., was born in Concord, Vt., on May 2, 1849. He graduated in 1875 from the New York Homeopathic Medical School, and for five years practised his profession in New Hampshire before removing to Stamford. He served as mayor of that city in 1910, having previously been its coroner and a member of the local board of health. He is survived by his widow and by three sons.

DR. GEORGE P. COOKE, who died on March 22 at Milford, Mass., was born in 1850. He graduated from the Harvard Dental College in 1869, and since that time had practised in Milford.

DR. A. WALDO FORBUSH, who died recently in Somerville, Mass., was born at Westminster, Mass., on Aug. 11, 1851. After graduating from Westminster Academy, he received the degree of M.D. in 1881 from the Eclectic Medical College, New York. He practised successively in Charlestown and in Somerville. He was a member of the Massachusetts Homeopathic Medical Society, and of the Massachusetts and Boston District Eclectic Medical Societies. He is survived by his widow.

DR. CHARLES LYMAN HODGKINS, who died recently in Park Falls, Wis., was born at West Roxbury, Mass., in 1870. He received the degree of M.D. from Georgetown University. During the Spanish War, he served as surgeon of the Seventeenth United States Regiment. Subsequently he practised successively at Castleton, Vt., Cotter Hill and Memphis, Tenn. He also worked for a time as sanitary engineer in Ecuador. He is survived by his widow.

DR. JULIA A. MARSHALL, of Norfolk Downs, Mass., died at Boston on March 26. She was born in 1841.

DR. VINCENT HAMILL, who died of heart disease recently in New York City, was born at Phoenix, N. Y., in 1873, the fourth generation in the direct line of a family of physicians. He attended Cornell University, and received the degree of M.D. from the Buffalo (N.Y.) Medical College. He is survived by his widow.

DR. JOHN WALDO JOHNSON, who died at Boston on March 24, was born on June 14, 1856, in South Framingham, Mass. He graduated from the Framingham Academy, and received the degree of M.D. in 1877 from the Harvard Medical School. He was a Fellow of The Massachusetts Medical Society. He is survived by his widow.

DR. JOSEPH F. NEE, who died recently in South Boston, was born at Scituate, Mass., in 1880. He graduated from Georgetown University in 1904, and since that time had practised dentistry in South Boston.

SOME PROBLEMS IN NEPHRITIS.*

By Horace D. Arnold, M.D., Boston.

During the past few years much attention has been given to the study of nephritis, both abroad and in America. Experimental nephritis in animals has taught us much in regard to these obscure conditions and will give us even more valuable information in the future. A number of new ways have been devised for studying the functions of the kidneys, and some of these are easily applicable to patients. In many other lines of investigation progress has been made. Enough has been done to show us that our old classification is unsatisfactory, and that many of our ideas were erroneous. The solution of many of the problems, however, has not been reached. The effect on the general practitioner has been to unsettle many of his convictions without giving him definite and reliable information to take their place. Have these investigations any practical bearing on the diagnosis, prognosis and treatment of nephritis? That is the question that the general practitioner asks,—and he asks it sometimes with some impatience.

It is not the purpose of this paper to give a complete answer to this question, for our knowledge on this subject is not yet complete enough to warrant definite conclusions. Neither will the attempt be made to make a systematic summary of our present knowledge and views of nephritis. This could be done properly only in a monograph,—not in an ordinary paper before a medical society. It has, however, seemed worth while to present to you some personal experience with some of the problems of nephritis, and to show to what extent these functional tests and other methods of investigation have been of value in dealing with these problems. Only a part of the field will be touched upon. Single typical cases will be used in the way of illustration, rather than any attempt to establish a point through the statistical compilation of cases.

The cases here presented belong mostly to the general class of cardio-renal cases, in which the condition of the kidneys is usually spoken of as chronic interstitial nephritis. This is a very comprehensive class, including cases that vary widely as to their cause and equally widely in their manifestations. In a large majority of these cases, as seen clinically, the cause of the disease cannot be definitely determined. In a number of cases the writer has been of the opinion that the most reasonable explanation lay in an excess of nitrogen in the diet.

In seeking an etiology for a given case of nephritis, we may consider the possible causes under three heads. 1. Microörganisms, which by locating in the kidney substance cause an inflammatory reaction. 2. Toxins, which may cause an inflammatory or degenerative reaction, depending on the kind and the strength of the toxic substance. 3. Circulatory changes, including both mechanical changes in the general or the renal circulation, and alterations in the vessel walls. In the class of cases which I attribute to an excessive amount of nitrogen in the food, the infections of the kidney may be ruled out, the circulation is essentially normal, and arteriosclerosis does not exist to a sufficient degree to cause definite degeneration of the renal cells. We must, therefore, look for our explanation in some toxic substance.

In these cases toxins from micro-organisms may be ruled out, except those which may be produced within the intestinal canal, and these may be disregarded practically if the bowels are kept freely open. Toxic substances from outside, such as lead and alcohol, have not been taken. We are, therefore, reduced to the consideration of toxic substances produced within the body by metabolism. We know that the chief function of the kidneys is to eliminate the products of nitrogenous metabolism, and that such substances, when not removed, act as poison to the system. If in sufficient amount, they produce the condition known as uremia.

According to the theory advanced above, the continued excessive ingestion of nitrogenous food (protein) taxes the functional power of the kidneys. An excess of nitrogenous waste material in the circulation may well be irritating to the kidneys, as it is to other organs and tissues. It is recognized that one such product, uric acid, does have such an effect, if in excess. Where there are no manifestations of gout, but a known excessive ingestion of protein, it seems probable that the trouble is due to an excess of some other nitrogenous waste product or products, whose identity is as yet unrecognized. If this is true, then the dictum, "Spare the kidneys by reducing the amount of protein in the food" is of great value as a preventive measure against nephritis, as well as the most important method of treating the disease when it has once been established. The following case illustrates this view.

Case 1. Male, 46 years, married, real-estate dealer. Heredity exceptionally good; from a long-lived family. Had always been in robust health; no venereal disease; no alcohol; tobacco in moderation. His habits were regular; he was an active business man, but without unusual business strain. There were none of the etiological factors usually spoken of in connection with chronic interstitial nephritis, but he was a hearty eater and habitually ate an excessive amount of meat. This, in my opinion, was the reason why at the age of 46 he showed an early stage of Bright's disease.

He was first examined in the spring of 1900. The urine showed the faintest possible trace of albumen and a few hyaline casts,—nothing else abnormal. The heart was moderately enlarged. The

* Read at a meeting of the Medical Section, Suffolk District Medical Society, January 21, 1914.

pulse was rapid,—100, and increasing to 112 on slight exertion,—and it showed high tension. No apparent arteriosclerosis. He complained of rapid heart action, nervousness, general malaise, and loss of appetite. This case would ordinarily be classed as one of primary chronic interstitial nephritis. He was placed on a somewhat restricted protein diet; he improved rapidly, and was not heard from again as a patient until June, 1905.

In June, 1905, he consulted me for a cold. It was found that the Bright's disease was in a much more advanced stage, although cardiac compensation had kept him relatively free from symptoms. After following the diet directions of 1900 for about a year, he had felt so well that he abandoned the restrictions and began to eat meat freely again. He was again placed on a low protein diet, with meat carefully restricted, and did very well until he had a retinal hemorrhage, about Jan. 1, 1907. He then consulted an oculist, who told him of the retinal hemorrhage and also stated that he had "advanced Bright's disease."

While this statement was true, the man's temperament was such that it was inadvisable to let him know how serious his condition was. I had spoken only of "kidney trouble" in terms serious enough to secure his thorough co-operation in dietetic treatment. He now became exceedingly worried and was unmanageable. He frantically tried one treatment after another that was reputed to "cure" Bright's disease. He abandoned each when it failed after a short trial, and sought my advice only at intervals. He grew rapidly worse, went abroad, against my advice, to consult European "specialists," and barely got home alive. He died in the spring of 1908 at the age of 54 years. No autopsy was allowed, but clinically it was a typical case of chronic interstitial nephritis. His death was due more directly to circulatory failure than to renal inefficiency, although at the very last there was a mild uremic condition.

One of the definite problems in chronic nephritis is the question of how much to tell patients about their condition. There can be no rigid rule. Each case must be judged on its own merits. Tranquillity of mind and a hopefulness for benefit, if not for a cure, are valuable aids to other forms of treatment. To most people the term "Bright's disease" means a warrant for a speedy death. The straight question, "Have I got Bright's disease?" is a hard one to answer, but it can generally be parried, or the affirmative answer can be so explained as to avoid the terror which people commonly associate with the name.

In this case the oculist made a mistake in telling him bluntly that he had "advanced Bright's disease." He added to his mistake by recommending an extremely limited diet, based chiefly on a certain kind of bread. This diet was, to be sure, very low in protein, but it was entirely inadequate for proper nutrition. When he returned to my care after a short interval, he had lost markedly in weight and strength, and the compensation of his heart was badly broken because of poor nutrition. This was the beginning of a rapid decline. As soon as his heart was somewhat improved he rushed off to one of the "water cures," and speedily broke the compensation again by overloading his circulation with large quantities of fluid. And so he went from bad to worse, and finally squandered what little strength he had left in a trip to Europe in the hope of getting better advice.

CASE 2 illustrated this problem, as well as demonstrating that our ordinary prognostic rules do not always hold true. I believe this case also was due chiefly to a high protein diet, although arteriosclerosis entered into the problem to some extent. When first treated he was 60 years of age. He had a good deal of arteriosclerosis. The urine was characteristic of chronic interstitial nephritis, as were also the cardio-vascular changes. He had just suffered a hemianopsia, which was apparently due to a slight cerebral hemorrhage. The prognosis as to duration of life would ordinarily be given as a very few years at most, yet this occurred fifteen years ago, and the patient today is considered a very well-preserved man for seventy-five years of age. He really considers himself too well to be under a doctor's care. He does not know to this day that he has any serious kidney trouble and he has lived comfortably and enjoyed life. His temperament is such, however, that if he had known the exact conditions he would have worried himself into his grave in short order.

Fifteen years ago a moderate regulation of his diet and the establishment of a regular regimen was sufficient to restore him to relatively good health. Ten years ago he had very mild uremic symptoms, and the dietary restrictions were increased. In the early spring of 1910 he again had a mild uremic attack, but refused to regard his condition as more serious than a "slight indigestion" until in June of that year he had a severe uremic attack. Since then he has followed the directions about diet very faithfully, and has remained well for three and one-half years. Except for mild cardiac stimulation and an occasional laxative pill, he has had no drug treatment.

In June, 1910, when he had his last uremic attack, his blood-pressure was 210. He was placed on a diet containing 70 grams* of protein and 2000 calories daily. Under this dietetic treatment his blood-pressure soon fell to 160, and it remained between 160 and 170 for three years,—until about six months ago. It has since then been gradually rising and now ranges from 180 to 200. His cardiac compensation is still good, however, and so far it has not seemed necessary to restrict his diet any more.

This case may serve as an introduction to the very interesting problem of the relation of renal inefficiency to high blood-pressure, including the question as to whether we can affect the blood-pressure in such cases by regulating the diet.

As a result of studying a large number of cases of chronic interstitial nephritis, I am convinced that in a great many cases the blood-pressure can be materially lowered by reducing the amount of protein ingested in the food. The

* The amount of protein taken by a patient is, of course, not known accurately,—as in an elaborate metabolism experiment in the laboratory. These figures are approximate only. However, the error is probably very slight, and they are as accurate as can be hoped for in practice.

basis for this belief lies in the fact that in so many cases the blood-pressure falls after such a regulation of the diet, when apparently all other conditions as to mode of life and treatment have remained the same. In these cases the low protein diet was employed at first on the principle of sparing the kidneys, and with no expectation of any effect on the blood-pressure. Observations on the blood-pressure were made as a matter of routine study. The frequency with which there was a fall in pressure and the amount of the reduction soon attracted my attention. It does not occur in all cases, but I think we must accept as a clinical fact that such a reduction is the rule rather than the exception in the class of these cases that are able to be about and can come to the doctor's office.

What the explanation may be is another matter,—the fact remains, and it is a most important factor in the treatment of such cases. Furthermore, the reduction thus obtained is usually greater than I have been able to obtain by any other method. In my experience vasco-dilator drugs rarely give a persistent reduction of more than 10 mm. Some time ago I tabulated my results from high-frequency electricity, and found the average reduction was from 10 to 15 mm. In those cases in which the blood-pressure falls as a result of a low protein diet, reduction of 20 to 30 mm. are very common, reductions of 30 to 40 mm. are far from rare, and I have seen a reduction of 60 mm. or more in a few cases. In those cases in which the heart is laboring to maintain an adequate circulation, a reduction of the pressure by 20 mm. or more is a most valuable aid in restoring compensation.

CASE 3 is interesting from the point of view of the effect of the diet on the blood-pressure, but it also illustrates the fact that in many cases by a proper regulation of the diet, life may be prolonged in advanced cases far beyond what we have been taught to expect.

This patient was a manufacturer, and was 61 years of age when he had his first uremic attack, about the last of October, 1908. The attack was so severe that for a time his life was despaired of. I saw him first on the second day of his second uremic attack, December 26, 1908. This attack was less severe than the first one, yet he was in a state of profound stupor, from which he could be aroused only with difficulty, and into which he sank again after a few moments. This was a case of chronic interstitial nephritis, with a moderate amount of arteriosclerosis. Renal inefficiency was marked enough to result in uremia, but the cardio-vascular system was in fairly good condition. This case, however, was not actually as advanced as the uremic attacks would seem to indicate. The chief reason for this statement is that under only moderate limitation of protein he lived a little more than three years and two months after I saw him first, and finally died of circulatory failure. He was found dead in bed on the morning of March 3, 1912. Except in his acute attacks the protein in his diet was not reduced below 70 grams daily, and it was often 80 grams or more.

In explanation I would say that I have taken 90 grams of protein as an entirely sufficient allowance for a healthy person, and as the maximum that any person should take when there is any question of impaired renal functions. I have taken 40 grams of protein as the lowest practical limit to be kept up continuously in cases with marked impairment of these functions, and have fed patients for months at a time at this lower limit. In proportion to the estimated severity of the case, the protein is reduced from 90 grams toward 40 grams. That this man could live over three years on a diet averaging about 80 grams of protein daily argues against an extreme impairment of the renal functions.

There was, however, a definite limit to the power of elimination by his kidneys, and if this was exceeded for any length of time he was soon in trouble. After the attack in December, 1908, he recovered his strength so quickly and felt so well that he could not be persuaded that continued restriction of the diet was necessary. However, a relatively short break from diet regulations caused a moderately severe uremic attack on May 5, 1909. After that he was more tractable.

At another time, when he was following his diet carefully at 80 grams of protein daily, he added green peas, on his own initiative. I had allowed him a certain list of green vegetables. He decided that fresh peas in the spring might be considered a "green" vegetable, not knowing that peas contain about 7 per cent. of protein. As he was fond of peas he ate them freely every day and unwittingly increased his protein by about 10 grams daily. This was the only departure from the authorized diet, yet after about ten days or two weeks this slight excess caused mild uremic symptoms.

We had, then, in this case a pretty sharply marked limit to the amount of protein he could take in his food. If he kept below this limit, he felt, to use his own words, "better than he had been for years." If he exceeded this limit for a short time, he lost his appetite and suffered from malaise; if he continued a longer time he had definite uremic symptoms. It seems clear that these symptoms, mild or severe, were due to the retention of nitrogenous waste products in the system, due to the ingestion of more nitrogenous food than the kidneys could eliminate.

This case illustrates especially well a variation in the blood-pressure corresponding with the excess of nitrogenous waste material in the blood. In his first uremic attack the blood-pressure is reported to have been 212. In the second attack I found it 190, but this observation was made shortly after a dose of nitroglycerin, and it probably had been over 200. Under a low protein diet the blood-pressure gradually fell to 160 on the thirteenth day after the uremic attack began. He was then able to come to my office and in the following

two weeks received eight treatments with high-frequency electricity. The average fall of blood-pressure at the end of each treatment was 10 m.m., although, of course, the effect of each single treatment on the blood-pressure was largely temporary. At the end of this period the blood-pressure had fallen to 140,—a total reduction of at least 50 mm.

In the attack in May, 1909, the reduction was even more striking. The blood-pressure was highest on the third day of the attack, when it registered 230. On the fourth day, 220; fifth day, 180; sixth day, 170. At this point he was able to sit up. On the eighth day it was 140. On the ninth day he was able to go out for a short walk. On the tenth day the blood-pressure was 135, and registered the same when he came to my office on the twelfth day. Here was a total fall of 95 mm. in 9 days, with no apparent explanation except that a low protein diet allowed the kidneys to eliminate the excess of nitrogenous waste material in the blood.

During the period of about three years when he was under treatment his blood-pressure would remain between 140 and 150 if he remained on a strict diet. However, although he reported for examination fairly regularly, he repeatedly broke over his diet restrictions, and thus gave an unusual opportunity to study the relation of a varying protein diet to blood-pressure. With an increase in the intake of protein the blood-pressure rose. The rise was roughly proportioned to the excess of protein, and not infrequently reached 170 or 180. Numerous other cases have apparently shown the same relation. Incidentally I may add that I have never seen any ill-effects from any reduction of the blood-pressure that resulted from, (or accompanied?) a low protein diet. It has been held by some authorities that a high blood-pressure in chronic interstitial nephritis is a conservative process and should not be interfered with. In this class of cases, of which I have given instances, nothing but benefit has followed such reduction.

But this is not the whole story. In other cases, apparently similar, no reduction of blood-pressure followed a considerable reduction of protein in the diet. It would appear that the conditions in these two classes of cases must be materially different, and we look to the newer methods of investigation in the hope that we may gain information which will enable us to differentiate the several varieties of disease which are now all included under the head of chronic interstitial nephritis.

A little more than a year ago, Professor Folin announced new methods of blood analysis by which could be determined with great accuracy the amount of nitrogenous waste products in the blood, and also the amounts of urea, ammonia, and uric acid. These methods are too difficult and delicate to be performed by practicing physicians, but the results are of great clinical importance in some cases. Folin states that in nephritis he has found the amount of nitrogenous waste products to vary from slightly above normal to four or five times as large as normal.

In cases of pronounced or threatened uremia the amount of waste nitrogen has been very high, otherwise the amount has not seemed to correspond to any particular clinical diagnosis. He also states that in these cases he has found "no correspondence between the blood-pressure and the degree of retention of the ordinary nitrogenous products." The amounts of these various substances in the blood are expressed in figures representing the number of milligrams in 100 grams of blood. In the cases which follow the amounts found will be stated in comparison with the normal amounts.

CASE 4. Merchant, 57 years. A case of moderately advanced chronic interstitial nephritis, moderate arteriosclerosis, and myocardial degeneration. In this case alcohol was an important etiological factor. He was a hearty eater and an estimate of his ordinary diet, recorded for three days, showed a daily average of about 140 grams of protein and over 3000 calories. The output of urea was approximately 20 grams in 24 hours, which is abnormally low for the amount of protein in the food. It seemed probable that there was retention of nitrogenous waste products in this case, and a specimen of blood was taken and sent to Professor Folin for examination. The report showed the amount of uric acid to be at the upper normal limit, the nitrogenous waste nearly twice the normal amount, and the urea once and a half times the normal amount.

The amount of protein in the diet was reduced from 140 grams to 70 grams, and the calories from 3000 to 2000. On this diet he had fewer symptoms and seemed to improve. Another specimen of blood was taken for examination 26 days after the first one. The uric acid had fallen from the upper normal to the lower normal limit, the nitrogenous waste was reduced one-third, but the urea was reduced only one-tenth.

The blood-pressure at the time of the first blood analysis was 195, at the time of the second analysis it was 185, and three weeks later it had fallen below 170. This is not as striking a fall in blood-pressure as has occurred in many cases, but it is a definite drop. The patient did not return for further observation, but we learned from his family physician that after a definite improvement he became careless about his diet and had resumed his alcoholic habits. The case shows by blood analysis a retention of nitrogenous waste, as was expected, and a definite drop in its amount when the amount of protein in the food was reduced. At the same time there was a definite fall in blood-pressure. So far this is the only one of my cases of this type in which this change has been followed through two blood analyses.

Correct, in this case, would seem to be our theory of impaired excretion, the retention of nitrogenous waste, and some relation between this and the blood-pressure. I believe this is a typical case of a certain variety of chronic interstitial nephritis. I have had the blood examined in a number of other cases which failed to give any confirmation of this theory. However, any

argument on a numerical basis among these cases would not be fair, for the other cases were the ones which had failed to respond to dietetic treatment. In other words they belong in a different class. Statistical arguments are valueless unless cases that are to be compared are so selected that they belong to a sharply differentiated class.

The figures in Case 4 are as follows:

	Uric Acid.	Nitrogenous Waste.	Urea Nitrogen.	Protein in Food.	Blood-Pressure.
Normal	1-2	24-26	12-13	90 grams	150
Dec. 12, 1912	2	46	19	140 grams	195
Jan. 7, 1913	1.2	30	17	70 grams	185
Feb. 1, 1913	—	—	—	70+ grams	170—

Case 5 is interesting in several respects, and shows among other things, that one normal blood analysis does not settle the diagnosis of the case. Accurate and reliable as this test is, nevertheless it throws light on but one factor in the clinical picture. It does not necessarily invalidate other evidence, and this case shows the value of considering all the features in the case in the interpretation of the significance of the blood analysis.

This patient was a married woman of 28 years. In 1910 she had eclampsia at the seventh month of her first pregnancy. She had albumen in the urine at that time, but the urine is reported to have been free from albumen since her recovery from that illness. In 1911 she had a miscarriage at about the third or fourth month of pregnancy, but there was no eclampsia. She has not been pregnant since. Early in 1913 her appendix was removed. No renal trouble was noted at the time of this operation. In the summer of 1913 her blood-pressure was found to be 200. I examined her first on September 23, 1913.

At that time the systolic blood-pressure was found to be 240, and the diastolic pressure was 120. The heart was moderately enlarged. There was a slight mitral regurgitation. It was reported that the urine had been examined recently and found to be normal. A single specimen at the time of my examination showed no albumen, but a centrifugalized sediment showed a few hyaline casts. One week later a twenty-four hour specimen showed the slightest possible trace of albumen by the nitric acid test, and the sediment contained a number of hyaline and fine granular casts.

The case appeared to be one of chronic interstitial nephritis. There seemed to be no etiological factor except the possibility that the trouble started from some one of the ordinary infectious diseases or a tonsillitis which she had had in childhood and early youth. It seems probable that it antedated the attack of eclampsia in 1910. She was anemic, the hemoglobin being down to 60%, and she had suffered from anemia five years before. It was my opinion that the slight mitral regurgitation was due to the anemia, acting through a poorly nourished left ventricle. She had had no symptoms and considered herself well, except for slight breathlessness on marked exertion.

An estimate of the diet for four days showed an average protein intake of 56 grams, but it had varied on the different days from 41 grams to nearly 70 grams. Her attending physician had reduced her allowance of meat to small amounts, so that she was already on a low protein diet, but with rather wide variations from day to day. The twenty-four hour amount of urea was 9.4 grams. —a low amount for a diet containing about 60 grams of protein. This fact, together with the evidence of the urinalysis led me to infer that she had chronic interstitial nephritis with impaired elimination and the retention of nitrogenous waste. The blood-pressure, however, was so high that it did not seem probable that it was due solely to the amount of nitrogenous waste that would be retained from so low an amount of protein in the diet.

On Oct. 1 a specimen of blood was taken for analysis. The report showed figures for uric acid, nitrogenous waste, and urea nitrogen that were about the low normal limit. At first sight this report would seem to indicate not only that there was no accumulation of nitrogenous waste in the blood, but that there was no nephritis. However, the other evidence seemed to indicate so clearly that this case was interstitial nephritis and that probably the power to eliminate nitrogen was impaired, that I looked for an explanation for the apparent discrepancy. It then appeared that on the day when the urine was collected, the day before the blood was taken for analysis, she had taken only 41 grams of protein. It therefore seemed probable that the kidneys could eliminate the amount of nitrogenous waste from this amount of protein and that this would explain the absence of any accumulation in the blood. Therefore this condition of the blood did not necessarily exclude nephritis. Her blood-pressure at this time had also fallen to 225.

As soon as the blood had been taken for examination she was placed on a diet containing 2000 calories and 60 grams of protein. This was not a lower amount than the average she had been taking, but it was thought that she would do better on a steady diet of this sort than on the wide variations her diet had shown before. On October 10 she was ordered a capsule three times daily, which contained 5 gr. of ferrous carbonate and 1-6 gr. of extract of nux vomica. This was given for her anemia and constitutes the whole of the medicinal treatment to date. On November 14 her diet was cut to 52 grams of protein, and on December 4 it was reduced to 44 grams. On that date the hemoglobin had risen from 60 to 80%, and the systolic blood-pressure had fallen to 200, although the diastolic pressure remains about the same, 120 to 125. She was appreciably better in every respect, and this improvement and the lowered blood-pressure seemed to be the results of a low protein diet.

Meantime, on Oct. 28, she entered the Peter Bent Brigham Hospital so that I might get a report on tests of her renal functions. While there, on a somewhat higher protein diet, another analysis of the blood was made and the amount of nitrogenous waste was found to be fully double the normal figure. In other words, this patient had a definite limitation to the power of her kidneys to eliminate nitrogenous waste. When the protein intake was sufficiently low there was no accumulation of these waste products in the blood, but when it exceeded the limit of excretion these waste products promptly accumulated in the blood.

A closer study of the output of urea in the urine showed that the action of the kidneys in this respect was sluggish. It was also shown that the elimination of salt was poor. On the other hand, the water balance was practically normal, and the tests for the excretion of potassium iodide and lac-

tose were normal. The phthalein test was nearly normal.

This case would ordinarily be classed clinically as one of chronic interstitial nephritis, yet it is distinctly different from the ordinary type of this disease. By means of the blood analyses and the tests of the renal functions we are able to show this, and we have received valuable information to guide us in treatment. Her protein intake should be kept as low as 45 grams daily and the amount of salt taken in the food should be limited. That the other renal functions are normal is valuable knowledge, and it possibly warrants a better prognosis than we should ordinarily give. I do not think we have yet accounted for her very high blood-pressure. Apparently this has been influenced to a slight extent by regulating the diet, but it would seem to be chiefly due to some other factor.

Certain aspects of Case V have brought us to the consideration of the clinical tests of the renal functions. These will be reviewed very briefly, with a few words of comment. The details of the technique will not be given, for lack of time.

The phenolsulphonephthalein test is supposed to measure the general excretory function of the kidneys. It is sometimes called the "phthalein" test or the "red" test, as a matter of convenience. Up to the present time it has been used more extensively in surgical cases than in medical cases. It has established a definite place for itself in surgery, especially in reference to the question of operations on the urinary tract. If the excretory power of the kidney is sufficiently low, operative measures should be postponed, if possible, until the renal functions have been improved by treatment, or in some cases they should be abandoned altogether. The mortality in several of these operations has been materially lowered through the intelligent interpretation of the results of this test.

This test has not been employed as extensively in the study of medical cases as in connection with surgical operations. It is, of course, equally accurate for medical cases, but the interpretation of the results is not so clear. It should be used more frequently in the study of such cases, and we may hope that with the collection of sufficient data this test will have a greater value in relation to the diagnosis, prognosis, and treatment. At present we may state that the percentage of phthalein excreted is reduced in cases of nephritis, and that the degree of reduction corresponds generally to the degree of impairment of the renal functions. In threatened uraemia the percentage is usually very low. Furthermore this test sometimes indicates a dangerous impairment of the renal functions, when other evidence of such a condition is lacking. On the other hand if other symptoms indicate danger, we should not disregard the warning because the phthalein test is essentially normal. Cases have been reported in which the phthalein test was essentially normal, yet uraemia followed in a very short time. A very low phthalein test, combined with a blood analysis which shows a large amount of retained nitrogenous waste, strongly suggests the imminence of uraemia.

We are not able to infer much from this test as to the duration of life, because we do not yet know how low the phthalein test may go and yet be compatible with a renal efficiency that will sustain life indefinitely, if the diet and regimen of the patient are properly adjusted. This is especially true of cases of interstitial nephritis which are stationary or are progressing slowly. This test, however important, is but one piece of evidence, and it must be considered in relation to all the other evidence in the case. The phthalein test gives no special indications as to the treatment of cases of nephritis, except in those cases where it indicates that uraemia is imminent. Here we would inaugurate vigorous measures earlier than if we depended solely on the other indications.

We now come to the consideration of functional tests which determine the power of the kidneys to excrete certain individual substances. The substances at present utilized for such tests are water, salt, nitrogen, lactose, and iodide of potash. Information about the excretion of the first three (water, salt, and nitrogen) has a distinctly practical bearing on the problems of treatment. If the kidneys have difficulty in eliminating any of these substances, it is common-sense to reduce the amount of work for the kidneys by reducing the amounts of the substances in question.

On the other hand these tests are supposed to be of value in diagnosis, enabling us to distinguish the cases in which the glomerular functions are impaired, those in which the functions of the tubules are impaired, and the mixed forms in which both systems are involved. It is generally agreed that the excretory functions of the glomeruli are different from those of the tubules. These tests, however, are based on the further assumption that we know what these different activities are, and that we can test these individual functions by these specific substances. Here we have left the solid ground of fact (or views about which there is general agreement), and have embarked upon the sea of theory (or views about which there is a definite difference of opinion). Will our boat, the working hypothesis of these tests, prove seaworthy?

It should be noted in this connection that we know far too little about the physiology of the kidney as a whole, and less about the normal or abnormal functions of its different parts. Furthermore there is a distinct lack of correlation between the clinical observations and the autopsy findings in many cases. The autopsies generally show that we are dealing with mixed

cases by the time death occurs, where both the glomeruli and the tubules are involved, although in the more acute fatal cases one system or the other is apt to be chiefly affected. Important work is now being done in experimental nephritis on animals, but it is not yet entirely clear how far the results are applicable to the nephritides of man, which are due to toxins of a very different character. It will require much more work along all these lines before we can form really reliable conclusions. The functional tests must be studied more extensively in connection with other clinical evidence, both of these must be better correlated with autopsy findings, and some of the problems can be elucidated by animal experimentation. In the meantime the assumptions on which these functional tests are based represent the opinions of men who are leaders in the investigations along these lines, and they may be accepted as the best working hypotheses available.

According to these views water and lactose are eliminated chiefly through the glomeruli, while sodium chloride and potassium iodide are excreted by the tubules. There is less definite agreement as to the place of excretion of nitrogenous material; therefore, as far as the localization of the functional disturbance is concerned, nitrogen has less significance than the four other substances.

Inability of the kidneys to excrete lactose in a normal way seems pretty clearly to indicate an abnormal glomerular function. Cases of this sort may be divided into two classes, those which show polyuria and those which show oliguria. Polyuria is considered to be due to a hypersensitive condition of the glomerular vessels, while oliguria is due to a hyposensitive condition. The ratio of fluid output to intake determines which condition exists.

Iodide of potash seems to be excreted by the tubules, but this test is perhaps less reliable and conclusive than the other tests. Salt seems to be excreted chiefly by the tubules, but the question of the amount of salt excreted depends not only on the functional power of the tubules but to some extent on the activity of the glomeruli. Normally the tubular epithelium appears to have the power of concentrating the urine by excreting an excess of salt ingested, even if the amount of fluid ingested is not increased. If the fluid intake is increased an excess of salt would be taken care of, at least to a certain extent, even if the concentrative power of the tubules were impaired, because of the increased outflow of urine. Therefore in this test we must take into consideration both the intake of salt and of water, and the output of urine and its concentration. Furthermore in the type of abnormal glomerular action in which the vessels are hypersensitive, salt appears to act as a diuretic and to increase the amount of urine. The functional activity of the tubules as to salt excretion is, therefore, tested by adding salt to the diet in considerable amounts without increasing the amount of fluid taken. If the tubules are normal and the glomerular action is normal this excess is eliminated in a concentrated urine. If the glomerular vessels are normal or hyposensitive and the tubules are impaired there will be more or less salt retention. If the glomerular vessels are hypersensitive, the diuretic action of the salt may make the test less conclusive as to the functions of the tubules, although if the tubular function is much impaired some salt retention will probably be found under these conditions.

Bearing the significance of these functional tests in mind, we may now consider Case VI,—one of the most puzzling cases of cardio-renal disease that I have studied.

CASE 6. This man was a traveling salesman for shoes; 45 years of age. He was first examined September 3, 1912. His history gave no probable etiology for his present trouble. He had never used alcohol to any extent.

His present trouble dated from February, 1911,—19 months before I saw him. The best information obtainable about an attack which occurred at this time would seem to indicate that it was uremia accompanied by a temporary aphasia and paralysis of his right hand and arm which lasted several hours.

In November, about nine months later, he fell unconscious and had more convulsions. The diagnosis, made by a very good clinician, was again uremia. After a few days in the hospital he returned home. Since then he had been in fair health, but had not returned to business. He complained of more or less malaise, loss of strength, some headache, and occasional attacks of dizziness. There had been no dyspnea on exertion, or other cardiac symptoms. He had noticed nothing unusual about the urine, but had been obliged to pass it two or three times during the night for a good while.

Physical examination showed an enlarged heart, the left border being 2 cm. beyond the nipple line. The heart action was strong and regular. There was a short, fine, high-pitched systolic murmur at the aortic area, and a lower pitched, rougher systolic murmur at the apex. There was moderate arteriosclerosis of the peripheral arteries, and it seemed probable that the aortic systolic murmur was due to arteriosclerotic changes at the aortic valve. The other systolic murmur was characteristic of slight mitral regurgitation. Compensation was good. The aortic second sound was much exaggerated. The pulse was 100, regular, and of very high tension. The systolic blood-pressure was 275, and the diastolic pressure was 190. There was moderate edema of the eyelids and slight soakage of all subcutaneous tissues, but no edema of the lower extremities that could be ascribed to broken cardiac compensation. He had recently consulted a good oculist, who reported to me that the fundi were normal except for definite evidence of arteriosclerosis. The physical examination was otherwise negative.

A single specimen of urine at the examination September 3 showed a specific gravity of 1010, acid, a slight trace of albumen, and a few hyaline casts.

The twenty-four hour urine, two days later, showed 1440 c.c.; specific gravity, 1012; acid; a very slight trace of albumen; many hyaline and a moderate number of fine granular casts; no other abnormal constituents in the sediment.

He had been requested to record his diet for the twenty-four hours during which he collected the urine, and a calculation showed that he was taking about 2100 calories and 96 grams of protein. The output of urea was 21.6 grams for the twenty-four hours,—a smaller amount than would be expected from the protein intake. The diagnosis of chronic interstitial nephritis seemed to be definitely established. There was moderate arteriosclerosis and cardiac changes secondary to the nephritis and arteriosclerosis. With a history of what appeared to be two uremic attacks ten and nineteen months previously, and with the extremely high blood-pressure, this patient seemed to be in a very advanced stage of the disease. The cardiac compensation, however, was unusually good, and the danger seemed to be more on the side of inadequate renal elimination and uremia than in the direction of the circulation. I assumed that the high blood-pressure was probably due to retained nitrogenous waste products, and, as he was taking a diet that was too high in protein for his kidney condition, I expected a definite fall in the pressure on a lower protein diet.

In this expectation I was entirely disappointed. Further observation of this case showed that the first observation of a blood-pressure of 275 was unusually low for him. It was usually considerably above 300. The exact figures cannot be given, as the scale of the mercury manometer did not go above 300. He was first placed on a 70-gram protein diet, and this was gradually reduced until on Nov. 12 he was ordered a diet containing only 52 grams of protein. On the lower protein diet the blood-pressure was more often between 275 and 300 than above 300, but, as it was at times over 300 and as it was only 275 at the first examination, it is not clear that the lower protein diet had definitely reduced it.

In other respects, however, he was distinctly better. His pulse was generally lower, frequently down to 88. He was practically free from headache, felt stronger and more energetic, and described himself on November 26 as "better in every way." The urine improved. The amount and specific gravity remained about the same. The casts diminished and disappeared on October 8, about one month after treatment was inaugurated. The albumen disappeared on November 11. The urea fell from 21.6 grams to about 13 grams in twenty-four hours on the reduced protein diet. These conditions remained essentially unchanged until early in January, 1913.

On January 14 a specimen of blood was taken for analysis. The result was essentially normal, the uric acid, nitrogenous waste, and urea being only very slightly above the upper normal figures. Professor Folin stated that this analysis was inconsistent with the results obtained in a large number of cases of nephritis, and raised a question as to the diagnosis. It seemed possible that the reduction of the protein intake might have reduced the amount of nitrogenous waste material to what the kidneys could eliminate, and that under these conditions a normal blood analysis would be consistent with the existence of nephritis. In order to test this idea, I increased the protein in his diet from 52 to 90 grams and asked him to continue at this diet for a month, unless he became decidedly worse. Inside of a week he telephoned to say that he did not want the full protein diet, that he found it difficult to force himself to take it, and that he was not feeling as well. I asked him to do the best he could for two weeks and then report.

On February 27 the blood was taken again for analysis. It was estimated that he had taken an average of 80 grams of protein for twenty days. The blood analysis was practically identical with the first examination. The amount of nitrogenous waste in the blood had not increased with an increased amount of protein in the food. The figures of the two analyses are as follows:—

	Uric Acid.	Nitrogenous Waste.	Urea Nitrogen.	Protein in Food.	Pressure. Blood.
Normal	1-2	24-26	12-13	90 grams	150
Jan. 14, 1913	2.3	30	15	52 grams	270
Feb. 27, 1913	2.2	28	16	80 grams	295

Besides suffering a return of his symptoms to a moderate degree, as a result of increasing the protein in his diet, the urine at this time, February 27, showed a return of albumen and casts after they had been absent in a number of examinations during the previous three months. The urea, which on February 7 was 13 grams on a diet containing 52 grams of protein, was now 18 grams, on an 80-gram diet. It was demonstrated that he did not do as well on a high protein diet. He was now allowed 70 grams of protein daily for a time. On this he felt better than when he tried to take 80 or 90 grams, but not as well as on the lower diet. He voluntarily cut below 70 grams in a short time and on March 28 he was again placed on a 52-gram diet. The blood analysis showed that the increase of symptoms was not due to retained waste products.

As he was feeling well again on his 52-gram diet, I had some difficulty in persuading him to submit to further tests. However, on May 2, I induced him to allow Dr. Reginald Fitz to try the phthalein test. The elimination of the dye-stuff was 14% for the first hour, when normally it should be 50%; and for two hours it was 28% instead of nearly 70%. This test indicated a marked impairment in the elimination by the kidneys, and confirmed the diagnosis of nephritis. In addition, Dr. Fitz found albuminuric retinitis with a slight hemorrhage, which further confirmed the diagnosis. He also found the systolic blood-pressure over 300.

A short time afterwards I persuaded the patient to go into the Peter Bent Brigham Hospital, so that the other tests of the renal functions could be made. The lactose test showed some impairment of the function of the glomeruli. Whereas in 5 or 6 hours at least 60% of the lactose should be excreted, only 50% was excreted in 7 hours. That this abnormality was of the type with hypersensitive vessels was shown by a polyuria when the amount of water was increased and a diuretic action by an increase in the amount of salt.

The tabular function of the kidneys was shown to be fairly good, because the concentration of the urine was somewhat increased when extra salt was given, notwithstanding the diuretic effects of the salt, and because iodide of potash was eliminated in a normal manner. The nitrogen elimination was somewhat below normal, but this had been shown not to result in nitrogen retention on a moderately high protein diet.

The results of these special examinations may be summed up as follows: The diagnosis of nephritis was definitely confirmed. It was shown that nitrogen and salt and water could be eliminated in fairly good quantities, and the danger of retention of these substances with resulting oedema and uraemia seemed remote. In this case the vascular changes seemed to predominate and the danger would consequently lie in overtaxing the circulation. For this reason, since nitrogen and salt both stimulated the hypersensitive blood vessels, these articles should be given sparingly. The cause of the high blood-pressure was not demonstrated. The whole case seemed to be one in which vascular disease predominated over the renal condition, and was more or less independent of the nephritis.

As far as treatment of this case is concerned this investigation merely gave additional reasons for continuing the low protein and low salt diet which had already been inaugurated. As far as diagnosis is concerned, while it confirmed the diagnosis of cardio-renal disease, it reversed the diagnosis as to the predominance of the two elements, the renal and the vascular. I had assumed from the history and the evidence that the kidney functions were so seriously impaired as to constitute the real source of danger. It proved, however, that the renal functions are fairly satisfactory and that the danger will lie rather with the failure of the circulation. This investigation also offered a better prognosis than I should have dared to promise without it.

During the past summer this patient lived a moderately active out-door life on the coast of Maine. He continued his 52 grams of protein in a salt-poor diet. He called to see me at the end of November. He looked in perfect health, and said he felt better than for years. However, his pulse was 92, his systolic blood-pressure was over 300 and the diastolic pressure 190, and the left border of his heart was 1 cm. farther to the left. So far he has had no medication except occasionally a grain or two of phenolphthalein to keep his bowels open. The present indications are to continue the same dietetic regulations, to avoid anything beyond moderate exertion, and later, if necessary, use cardiac tonics when the heart begins to fail.

As we accumulate more data, we shall undoubtedly divide our cases of chronic interstitial nephritis into at least two or three clinical types. A better insight into these cases should lead to better treatment and more benefit. Even advanced cases of Bright's Disease of the ordinary type, may be benefited. If we can regulate the diet so that the nitrogenous output is within the capacity of the kidneys and the patient still gets sufficient nutrition, many of these cases may live in comfort for years longer than we have been taught to expect.

In conclusion,—what practical deduction can we draw from the consideration of the problems presented by these cases.

Cases of nephritis do better on a low protein diet, which requires less functional activity on the part of the kidneys. The degree to which the protein should be cut down depends on the degree of impairment of the renal functions. A rough estimate can be made on the basis of allowing 90 grams of protein in the lightest cases and about 40 grams in the severe or advanced cases. Intermediate grades should have an amount of protein between these extremes, varying according to the severity of the disease. If the symptoms improve and the blood-pressure falls, the functional tests are not essential; otherwise valuable information may be obtained from them, even in the present stage of our knowledge. With the accumulation of more data, the inferences that may be drawn from these functional tests will be more and more valuable.

In cases with oedema, and also in the cases in which the blood-pressure remains high although the protein in the food is reduced, the amount of salt should be reduced.

As a result of further study, we shall undoubtedly divide our cases of chronic interstitial nephritis into at least two or three clinical types.

A better understanding of these cases and a more careful study of the problems of nephritis will lead to more intelligent treatment and resulting benefit to the patient. A proper regulation of the diet,—not forgetting to provide a sufficient amount of nutrition,—will enable many of these patients to live in comfort for years longer than we have been taught to expect.

THE IMPORTANCE OF DIAGNOSIS AND TREATMENT OF PRIMARY SYPHILIS.

By C. Morton Smith, M.D., Boston.

The treatment of syphilis of the central nervous system, tabes and general paralysis is receiving widespread attention at present both in the clinic and laboratory. Syphilis was not recognized as the etiological factor in tabes and paresis until recently. These conditions were classed as para-syphilitic affections, *i.e.* syphilitic in origin but not in character. Mercury and iodides had slight control over the progress of the disease in these cases, and with no exact knowledge of how these degenerative changes occurred, it was claimed they were due to toxines or by-products of the infection and corresponded with the nerve changes after diphtheria.

Noguchi's demonstration of spirochaetes in the brain tissue of paretics and the successful inoculation of rabbits with the spinal fluid of tabetics shows beyond a reasonable doubt that

we are dealing not with the action of toxines but the direct effect of the spirochaeta pallida. However, the fact remained in regard to the slight success of the old-time treatment.

Some tabetics responded to intravenous injections of salvarsan, but with many it was inefficient and paretics were not improved. Attention was called by Camp to the fact that arsenic was not found in the cerebro-spinal fluid in cases that had received salvarsan intravenously. This is said to be due to the selective activity of the choroid plexus, which allows only certain substances to pass from the blood stream into the ventricles. Flexner's work on meningitis suggested intraspinal injections, and Swift and Ellis devised their method of preparing and introducing salvarsanized serum. Following their lead, much careful work is being done along these lines and the results already obtained amply justify a continuation of this method of treatment as the process seems to be arrested or perhaps cured in some, while other cases are relieved of distressing symptoms.

The object of this article is to emphasize the importance of early diagnosis and prompt energetic treatment, for therein lies the reasonable hope of safeguarding the patient against these serious nerve lesions already mentioned.

During the comparatively short time that salvarsan has been in use a fairly definite method of application has been developed whereby it seems possible to sterilize the individual before the nervous system has been invaded. When energetic treatment with salvarsan and mercury is begun during the early primary stage the disease can be aborted in a large percentage, if not in all cases. If treatment is delayed until the secondary stage or later, it is still usually possible, but more difficult, to bring about the desired serologic change.

Syphilis may invade the central nervous system during the secondary stage and may or may not cause clinical symptoms. Hence, Bernstein advocates an early lumbar puncture in all cases of syphilis to determine the cell content of the spinal fluid, this being a more accurate guide to cerebro-spinal syphilis than the Wassermann reaction on blood serum or spinal fluid. He also favors a routine intraspinal injection of salvarsanized serum as a precautionary measure.

There is still need of an intimate clinical knowledge of syphilis although the diagnosis of a primary lesion no longer rests on clinical examination alone. Spirochaetes can often be demonstrated in primary sores only a few days old, either by the dark-field microscope, or in stained preparations. The latter is best suited for the general practitioner as no special apparatus is needed.

Many patients are exceedingly optimistic regarding their own possible primary lesion and lose valuable time before seeking advice, believing it to be only a "cold sore" or "chafe." Further time is also lost in some cases if we can believe the patient's statement that "the doctor said it was a soft sore and did not amount to anything," and later when a roseola appeared, explained that "it had backed up into the system."

In the out-patient department of a large hospital the writer has been surprised at the small number of patients with primary syphilis or questionable lesions seeking or sent for advice or treatment. Not only does the welfare of the patient call for an early diagnosis, but the safety of the public also demands prompt recognition and healing of primary sores. Many small epidemics have been traced to an unrecognized primary lesion of the finger, lip or elsewhere. Numerous instances of this sort are on record, one of the latest being Schamberg's report of practically a dozen cases of infection about the mouth traced to a young man with a primary lesion of the lip who attended a party where kissing games were played.

There is still the same old necessity for a positive diagnosis before beginning treatment, but with the means already mentioned it is often possible to make a definite statement at the first visit. Failing to find spirochaetes the Wassermann reaction usually becomes positive three or four weeks after the appearance of the sore.

It is also important that the treatment begun early should be continued until a serologic as well as symptomatic cure is obtained. The Wassermann test is of value to the clinician as a measure of treatment, as well as an aid to diagnosis. A weakly positive reaction in a known syphilitic, or where the reaction has been strongly positive is an indication for further treatment. In a case for diagnosis, lacking history and clinical evidence, a weak reaction should be disregarded.

The treatment of early syphilis should comprise three to six intravenous injections of salvarsan given at ten-day or two-week intervals and supplemented by mercury, preferably by intramuscular injection. The effect is determined by a Wassermann test six to eight weeks after treatment has been omitted. If the test is positive the course of injections should be repeated. When such treatment is begun in the primary or early secondary stage a permanent negative test should be possible in six to nine months in the majority of patients.

By early diagnosis and active treatment we can hope to accomplish the following:—

1. Abort the disease in a large number of cases.
2. Protect the family and community.
3. Prevent the probability of transmission of syphilis to the offspring, some of whom may become a burden to the state.
4. Lessen the possibility of the so-called neuro-recurrences.
5. Probably safeguard the individual against late nerve syphilis,
6. Thus diminishing the likelihood of their becoming useless members of society, if not state charges.

Clinical Department.

A CASE OF BONE CYST OF THE OS CALCIS.

By Wm. Pearce Coues, M.D., Boston.

Bone cysts other than those found in the long bones are of such uncommon occurrence that the report of the following case is of interest. In a cursory examination of the literature on this subject, I have been unable to find a similar case.

A. L. 14 years, was seen Sept. 5th 1913.

Past History. The mother and father are living and well; one brother died in infancy of gastroenteritis; one brother and two sisters are living. One of the sisters is of a nervous temperament, with much digestive trouble. The patient's past history is not important concerning this trouble.

Present Illness. There is trouble in the other heel, the right, since last May, when he fell directly on the heel while doing gymnasium work. This foot bothered him off and on since, with considerable aching at times. The pain especially noted after walking or running. Absolutely no symptoms from the left heel, the seat of the bone cyst.

Examination showed a well nourished boy. The right heel was painful to pressure over the epiphysis of the os calcis. There was no abnormal thickening made out. X-ray of this foot showed an old separation of the epiphysis of the os calcis.

Bone Cyst.
Left os calcis. Male, 14 years.

An x-ray of the left foot was taken for comparison. This picture showed a bone cyst of the body of the os calcis. The whole of the central portion of the body of the os calcis was involved, the thinning extending down apparently quite close to the plantar surface of the bone. Immediate intervention was not advised, but observation at short intervals with radiographs for comparison with the first picture, and operation, should the slightest symptoms arise, was urged. Some two months after this the patient was heard from. The trouble had given no symptoms up to that time.

Medical Progress.

A REVIEW OF THE PROGRESS IN PATHOLOGY FOR 1913.

By S. B. Wolbach, M.D., Boston,

Assistant Professor of Bacteriology, Harvard University Medical School.

CONTENTS.

Tumors:

Acid Agglutination of Bacteria.
Experimental Nephritis.

It is hardly to be expected that notable contributions in gross and microscopic pathological anatomy will be made each year, because of the highly developed state of our knowledge on these subjects. The bulk of the work done along these lines is too highly specialized to be of general interest. Some of the most notable contributions to pathological histology, which represent many years of investigation, have been made by Mallory, in his text-book, "Pathologic Histology." Of special note are his contributions to the histology of early syphilitic lesions, trichinella spiralis, the histology and classification of tumors, infectious lesions of the heart, blood vessels and kidneys and the pathology of the liver.

The contributions in the field of experimental pathology from America are perhaps more noteworthy than those from abroad where the corresponding type of work is done in closer connection with the clinic, and in the main is represented by diagnostic and metabolism experiments upon patients.

TUMORS.

A valuable contribution for those who deal practically with tumors is to be found in Mallory's text-book, "The Principles of Pathologic Histology." This book contains an admirably simple and adequate classification upon a histologic basis, and the different tumors are well illustrated and described with great clearness.

Rous and Lange (*Journal of Experimental Medicine*, Vol. 18, No. 6, p. 651) report the find-

ing of a third transplantable chicken tumor due to a filterable cause. This third tumor is a sarcoma having characteristic intracanalicular arrangement in relation to blood sinuses which accompany the growth. Like the other two chicken tumors described by Rous, a spindle cell sarcoma and an osteochondro-sarcoma, this one is due to an agent which will pass through Berkefeld filters.

Henke and Schwarz (*Deut. Med. Woch*, Vol. 40, No. 6, p. 67) claim to have transmitted a mouse carcinoma by injection of cell-free filtrates. The tumor was one propagated by them from a spontaneous mammary carcinoma of unusual virulence. The technic was to grind up the tumor in sterilized salt solution by means of sand. The emulsion was centrifugalized and filtered through ordinary filter paper. The filtrate is said by the authors to be cell-free.

Tyzzer (*Journal of Medical Research*, Vol. 28, No. 2, p. 309) has contributed some valuable experimental evidence concerning factors in the distribution and growth of tumor metastases. Tyzzer made use of the carcinoma of the Japanese Waltzing mouse, which was originally propagated by him from the spontaneous tumor discovered several years ago. In all, 157 inoculated animals were utilized and manipulated in various ways. He found that metastases may be artificially produced by the manipulation and massage of the implanted tumor, and that this is accomplished as readily during the early development of the tumor as in the later period in which metastasis naturally occurs. Incomplete operations involving the incision of implanted tumors do not increase the incidence of the metastases, but the metastases that result grow more rapidly if a large amount of the original tumor mass is removed. Radical operations involving removal of all the tumor, when performed just prior to the period in which metastasis commences, results in a temporary freedom from this complication, even though recurrence commonly occurs. The clinical inferences to be drawn from this work are obvious.

HODGKIN'S DISEASE.

Renewed interest in the etiology of this poorly defined disease is awakened by reports of the cultivation of a diphtheroid bacillus. The first account is by Negri and Mieremet (*Cent. f. Bak. Orig.*, Abt. 1, bd. 68, heft 3-4, p. 292) who cultivated from two cases, a bacillus having distinctive cultural and morphological characteristics. Their animal experiments on guinea pigs, rabbits, mice and monkeys did not give conclusive results, and for the greater part were negative. In the introduction to their paper, the authors call attention to the fact that Fraenkel and Much found bacilli, morphologically similar, in cases of Hodgkin's disease, by the antiformin sedimentation method. Eleven cases which were proved not to be tuberculosis yielded the diphtheroid bacillus. A number of other observers confirmed this work before the time of publication by Negri and Mieremet. The authors believe their cultures to be identical with the bacilli found by Fraenkel and Much.

In this country, apparently stimulated by the work of Fraenkel and Much, and independently of Negri and Mierement, Bunting and Yates (*Arch. of Internal Medicine*, Vol. 12, No. 2, p. 236) report the cultivation of the diphtheroid organism from three cases of Hodgkin's disease. In later publications (*Journal American Medical Association*, Vol. lxi, No. 20, p. 1803, and Vol. lxii, No. 7, p. 516) they report inoculation experiments in five monkeys which reacted in a manner suggestive of Hodgkin's disease. The authors lay stress on the fact that the blood picture in these monkeys was similar to that which is found in man in the early stages of the disease.

Billings and Rosenow (*Journal of the American Medical Association*, Vol. lxi, No. 24, p. 2122) report the cultivation of the same bacillus in twelve cases. No animal experiments are recorded. The cultures were utilized for vaccine treatment of the disease with results suggestive of improvement.

Steele (BOSTON MEDICAL AND SURGICAL JOURNAL, Vol. clxx, No. 4, p. 123) reports the finding of the same bacillus from a case of Hodgkin's disease, and from a case of lymphatic leukemia.

It is difficult to appraise the importance of these papers. They are certainly highly suggestive that the commonest form of chronic glandular enlargement known as Hodgkin's disease is infectious and due to a bacillus closely related to the diphtheria bacillus on the one hand and the tubercle bacillus on the other. The animal experiments so far recorded cannot be taken as conclusive; they are merely suggestive and the lesions obtained are such as would result from an extremely attenuated tubercle bacillus or even by attenuated pyogenic bacteria. It is true that the lymph nodes draining the regions inoculated show chronic inflammatory changes and necrosis, but it must be remembered that the inoculations were repeated several times in the same animal. The metastases of the lungs, liver, heart and pancreas were in the nature of abscesses and did not simulate the metastatic lesions in man.

In this connection one must also take into account that diphtheroid bacilli are frequently encountered in human tissues. The most notable instance is in leprosy, where they have frequently been encountered in all parts of the world (Wolbach and Honeij, *Journal of Medical Research*, Vol. xxix, No. 3. p. 367). These observations will undoubtedly stimulate research regarding the occurrence of bacilli in normal and diseased tissues, other than Hodgkin's disease. In the absence of a perfectly characteristic reaction in animals, proof depends on indirect methods, such as the obtaining of

characteristic immune reactions and statistical studies.

COMMUNICABLE DISEASES.

Non-Infectious Tick Bite Disease. Todd in 1912 (*Canadian Medical Association Journal*, Vol. ii, No. 8 and No. 12) calls attention to a peculiar disease of children associated with the bites of ticks. The tick is the same one that transmits spotted fever in Montana. The symptoms are those of an acute ascending paralysis. Recovery takes place after removal of the ticks.

Bishop and King (*Journal of Economic Entomology*, Vol. vi, No. 2) in a study of the spotted fever tick record nine cases of paralysis in which the symptoms subsided rapidly after the removal of the ticks. They know similar cases reported from Wyoming.

Eaton (*Australasian Medical Gazette*, Vol. xxxiii, No. 17) reports the case of a child with temperature and paralysis of the legs and thighs, who recovered rapidly after the removal of a tick which was attached over the right scapula. He quotes other similar cases noted by Cleland in Australia.

It is hardly possible that a disease of this nature could be caused by an infectious agent, but coming from such widely different sources, it is not possible to doubt the accuracy of the observations, and we must accept the fact of a new disease, caused by bites of ticks, and probably dependent upon the injection of toxic substances.

Verruga Peruviana, Oroya Fever, Uta, Strong, Tyzzer, Brues, Sellards and Gastiaburu (*Journal of the American Medical Association*, Vol. 61, No. 19) give a preliminary report of the first expedition to South America from the Department of Tropical Medicine of Harvard University. They have shown that verruga peruviana and oroya fever are separate diseases, contrary to the generally accepted idea that the latter is an acute stage of the former. They accept as a cause of the diseases bodies found in the red blood corpuscles, originally described by Barton, Gastiaburu and Nicolle. The nature of these bodies has been disputed but Strong, Tyzzer and their associates have definitely decided that they are parasitic in nature and have created a new genus, Bartonia, for these parasites. The authors have succeeded in transmitting verruga peruviana to animals,—monkeys, dogs and rabbits. An inoculation experiment done on a volunteer produced only local papules. There was no fever, no eruption and no blood changes, such as occur in oroya fever.

Uta is a disease known from prehistoric times in Peru and is a destructive granulomatous process involving the face. The members of the expedition have found the parasite of this disease, which is a leishmania.

(To be continued.)

RECENT PROGRESS IN GENITO-URINARY SURGERY.

By Francis S. Watson, M.D., Boston,

and

Paul Thorndike, M.D., Boston.

KIDNEY.

Infantile Kidney. Geraghty and Plaggemeyer.[1] Three thousand, nine hundred and forty autopsies at the Johns Hopkins Hospital show three cases of the above type where a large hypertrophied kidney existed on one side and a small so-called infantile kidney on the other side.

CONCLUSIONS.

The diagnostic points in determining the presence of a kidney of the type presented above, may be summed up briefly as follows:

1. When disease is present in the larger, hypertrophied kidney, the total function, as estimated by phenolsulphonephthalein, is decreased, and the function of the diseased kidney is usually greater than the function of the supposed healthy kidney.

2. The function of the infantile kidney shows marked decrease, although the urea percentage and general character of the urine is normal, while the amount of urine secreted is relatively small.

3. Pyelography is of doubtful value, since the size of the kidney pelvis is usually not a reliable index of the size of the kidney.

4. In persons not too stout it may be possible to secure Roentgen-ray shadows, showing the presence of a diminutive kidney.

In Case 7 considerable diagnostic help was obtained from the Roentgen ray, which showed a very small kidney shadow, less than half that of the opposite side. This, taken in conjunction with the functional findings and the character of the urine, was of considerable diagnostic aid.

In conclusion, it may be emphasized that kidneys of the infantile type are a menace to the surgeon if the opposite kidney is the seat of the disease. The character of the urine may be normal in appearance and the urea concentration or percentage may be high. The recognition of this anomaly may be extremely difficult, and its presence can be suspected only when function estimations are carried out.

Tests of Renal Function. The Blood-kidney Index in Kidney Disease. Bromberg[2] says that the chlorides in the blood and in the urine afford a most valuable means of estimating renal function. He says that normal concentration in the blood is just half that in the urine, and he calls this ratio of 1 to 2 the hemo-renal index. He claims that a change in this index points to trouble sooner than any other sign, and that as

soon as this ratio becomes less than 1 to 2, some serious disturbance should be looked for. If the ratio becomes less than 1 to 1.5, operation of any sort is contraindicated. The author has made a small electric apparatus by which he computes easily the amount of chlorides in the blood and urine by comparing their electric conductivity. This apparatus is illustrated and described. It requires only a few drops of blood and of urine for the performance of the test.

Fluorescein Test. Strauss,[3] in thirty cases, found that if one gram of fluorescein-sodium be given by mouth, a fluorescent urine was passed in from ten to twenty minutes, and that this fluorescence disappeared after thirty-five to forty hours. He thinks these facts may be made the basis of a valuable renal test which will be extensively used because the drug is taken by mouth instead of under the skin, and the technic is so much simpler than that of the tests now commonly in use.

Chromo-ureteroscopy. Thomas[4] believes that chrono-ureteroscopy, based on the employment of indigocarmin, is the most valuable single test for renal sufficiency or insufficiency that we possess, because it is the most practical, affording the same diagnostic advantages as the functional tests dependent on bilateral synchronous ureteral catheterization, the technic and determination of which are tedious, complicated and consume much more time. Comparative observations of the onset and intensity of the color elimination have never failed to determine the functional sufficiency of the supposedly normal twin organ in view of operative intervention. It is of no value in movable kidney, in the presence of ureteral kink or hydronephrosis, pyelitis, essential hematuria, or early tuberculosis. It is of value in the differential diagnosis of hemorrhage and chronic interstitial nephritis from other types of the disease.

URETERO-VESICAL VALVE.

Braasch[5] discusses the advisability of cutting the uretero-vesical orifice either through a suprapubic incision or through an operative cystoscope for the purpose of removing the stones from the lower end of the ureter. He reiterates the fact that this uretero-vesical valve exerts, under certain conditions, a check-valve action which, however, is of questionable value in preventing a reflux of urine from the bladder. He reports his own experiments and concludes as follows:

"Tentatively we conclude that in experienced hands there is little or no danger in human beings from the operation of meatotomy through the operative cystoscope, either as regards immediate hemorrhage or sepsis, or as regards late results from injury to the kidney.

"The protection from reflux is affected at least as much by physiological function of the ureter as by the check-valve action at the meatus. These together, rather than the uretero-vesical valve alone, constitute the 'factor of safety' which prevents reflux.

"The ureter alone, almost without exception, sufficed experimentally to prevent reflux, even if the uretero-vesical valve had been destroyed. Section of the valve appeared to leave the protective ureteric function intact.

"The above data would confirm the opinion expressed by others that renal infections are seldom if ever ascending, but rather hematogenous in origin."

Intra-dural Route, Anastomosis, for the Relief of Paralysis of the Bladder. Frazier and Mills.[6] The authors describe in detail a remarkable operation of nerve-root crossing by which an anastomosis between the first lumbar and the third and fourth sacral nerves was accomplished. They claim that such a procedure has a place in surgery, especially in the paralyses of the bladder and rectum following trauma, and they conclude their admirable paper in part as follows:

"If this new plan of procedure had no other application than for the relief of the vesical palsy it would still have a wide and important field. That it is based on a reasonable hypothesis has been proved by experimental observations on the lower animals; that it is a justifiable risk no one will gainsay; that it gives promise of attaining its object has been demonstrated by the fact that our patient has already gained some control of the bladder."

PROSTATE.

Radium in the Treatment of Prostatic Cancer. Pasteau and Degrais.[7] At the present time, when surgery offers so little relief for prostatic cancer and when radium is being hailed as cancer's most powerful enemy, this article is of interest. The authors have used radium on fifteen patients, among whom were two physicians. The radium was introduced into the full bladder by means of a narrow tube, which is described. It is left in place three or four hours, and six exposures are made at intervals of three to six days. Similar exposures may be made through the rectum or through an incision in the perineum or into the bladder from above, as well as through the ureter. Improvement is claimed in every one of the fifteen cases.

A New "Punch Operation" for Small Prostatic Bars and for Contractures of the Prostatic Orifice. Young[8] describes an instrument for punching out pieces of tissue for the relief of obstruction due to small prostatic bars or to contractures or lobules not associated with lateral hypertrophy of the prostate. He says that in such cases the operation is radical, does not have to be repeated, does not require subsequent urethral dilation and does give lasting cures.

The Human Prostate Gland at Birth. Lowsley[9] spent many months studying serial cross sections of the prostate of a baby. The results of his work are embodied in a wax model which maintains exactly the normal relations of the

structures studied, and which demonstrated admirably certain facts of real surgical value. For example, two large lobules in the outermost portion of the lateral prostatic globes send branches in a direction away from the bladder. All other lobules extend towards the bladder. In most successful enucleations the two forward branches are found extremely adherent and must be cut across. Again, he shows how cancer and hypertrophy may exist together and how the hypertrophied lobe may be so distinctly capsulated as to resist the invasion of cancer and so oblige it to travel in other directions. This is a most interesting and instructive paper of great value.

TESTICLE.

Paths of Infection in Genito-urinary Tuberculosis. Walker [10] offers evidence (clinical, pathological and experimental) which he thinks goes to show that tuberculosis infection of the testis takes place by extension down the cord and not through the blood stream. He does not deny that the latter form of infection may exist, but says it is rare. The evidence he quotes as follows:

"Clinical evidence: 1. It is extremely rare to find tubercle of the epididymis without discovering some indication of disease of the prostate or the vesicles. 2. Prostatic tubercle is not infrequently found without any lesion of the testicle. 3. The appearance of a tuberculous epididymitis is often preceded by symptoms of prostatitis or vesiculitis—the so-called prodomata of tuberculous epididymitis. 4. The earliest signs of tuberculous disease are found at the lower pole of the epididymis. This is the first position which opposes the line of march of the invading organisms. 5. Tuberculous disease of the testicle is analogous to acute infections which are known to have been produced by extension from the urethra. The ordinary type of tuberculous epididymitis has no analogy to the hematogenous orchitis of mumps. Pathological evidence: 1. Lesions of the testicle without disease of the prostate are rare whereas tuberculous lesions of the prostate are not infrequently found unaccompanied by disease of the testicle. 2. When tubercle of the testicle is found in association with tubercle of the prostate, the lesions in the prostate generally have the appearance of being older than the lesions in the epididymis. 3. Tuberculous nodules in the lower pole of the epididymis usually appear older than those in the upper pole. They are the first to soften and break down. Experimental evidence: 1. Microorganisms and inanimate granules are rapidly absorbed from the urethra and carried to the testicle. 2. A tuberculous epididymitis may be experimentally obtained by inoculating the urethra, after having damaged one of the testicles." This work is recorded because it is so at variance with commonly accepted beliefs.

Transplantation of the Testicle. Lespinasse.[11] The author reports a most remarkable case in which slices of a recently removed healthy testis were transplanted between fibres of the rectus muscle and also into the scrotum of a man who had lost both testicles and was impotent. "On the fourth day after the operation, patient had a strong erection accompanied by marked sexual desire. The man has, since the operation, regained his sexual powers completely, both as to desire and as to ability. Furthermore, these powers have remained present for two years." A description of the technic of the operation follows

"A man, aged 38, consulted me in January, 1911, to find out if anything could be done for the loss of both testicles. One testicle which had been retained was removed during a hernia operation; the other had been lost by an accident about two years previous to his consultation with me. He was unable to have intercourse, which was his chief reason for coming to me.

"A testicle from a normal man was easily obtained. In fact, I was surprised at the number of testicles that are available for transplantation purposes.

"The two patients were anesthetized at the same time, and the recipient prepared as follows: The scrotum was opened high up and a bed prepared in the same way as we prepare the bed for the reception of an undescended testicle. Hemostasis was carried out with great care. Another incision was made over the rectus abdominalis muscle; this incision was carried down through the skin and fascia. The fibres of the rectus muscle were exposed and these fibres separated by opening an artery and forceps plunged into the muscle. Hemostasis was carried out and then the testicle to be transplanted was removed. It was immediately stripped of the epididymis, cord and tunica vaginalis, and then sliced transversely to its long axis, these slices being approximately 1 mm. in thickness. The central slice and the one next to it were taken out and placed among the fibres of the rectus muscle. Another slice was placed in the scrotum. The wounds were closed without drainage and healed by first intention throughout."

SEMINAL VESICLE.

Belfield.[12] In these two short articles, illustrated by radiographs, the author describes the technic by which collargol or some equivalent metallic compound may be injected into the vas deferens and so up into the seminal vesicle through a small scrotal incision opening into the vas just above the testis. The incomplete work Belfield had done has already demonstrated several important facts, namely, the existence of a peristalsis of the ampulla and vesicle into the prostatic urethra and sphincteric closure of the ampulla and vesicle; the occasional blockade of the ejaculatory duct," converting the vas and vesicle into a retention cyst."

GONOCOCCUS.

Gonococcus Vaccines and Glycerine Extracts of the Gonococcus in the Diagnosis of Gonorrheal Infections. G. C. Shattuck and W. S. Whittemore.[13] Persons suffering from infectious diseases often demonstrate certain changes in the blood serum. These changes are believed to be responsible for certain reactions, like that of tuberculin, and a few investigators believe they have found in the serum of gonorrheal persons changes which they believe to indicate a specific reaction for gonorrhea. The authors of this valuable article hoped to find "a reliable method of diagnosis for gonorrhea by means of a specific reaction." Their conclusions follow:—

"*a.* From published work of others referred to above:—

"1. Reactions thus far observed after injections of gonococcus vaccine have not been clearly specific for gonorrheal infection.

"2. The reactions seem to show a selective action in some types of gonorrheal disease.

"3. Local reactions after injections are common in non-gonorrheal cases. They are not valuable for the diagnosis of gonorrhea or for demonstration of its cure.

"4. Focal reactions are seen frequently in active gonorrheal arthritis and salpingitis; but, whereas they have been observed in cases showing no other evidence of gonorrhea, their diagnostic value is small.

"5. A general reaction is seldom noticeable, and it may be easily simulated by slight symptoms due to other causes. It has *per se*, no diagnostic value.

"6. Gonococcus vaccine autolyses rapidly, and thus undergoes changes little known.

"*b.* From writers' work:—

"1. The concentrated vaccine used by the writers showed no superiority for diagnostic tests.

"2. It produced in gonorrheal and in control cases a local lesion like that of a chemical irritant. We think that autolysis may have been a factor in producing the supposedly irritating properties of our vaccine; that the changes in the vaccine may have prevented it from producing a specific reaction; and that the unsatisfactory therapeutic effects of gonococcus vaccine may, perhaps, be traceable to autolysis.

"4. Glycerine extracts of the gonococcus inoculated by the method of von Pirquet caused, in a few cases, the formation of peculiar papules which may have represented a specific reaction. Most of the cases showed no definite reaction.

"5. Although our tests were negative in the main, and although the work of others using similar methods has yielded unsatisfactory results for diagnosis, we desire to emphasize our belief that failures serve as guideposts to progress, and that present knowledge justifies the hope that a valuable diagnostic test for gonorrheal infection may yet be devised through improved methods of preparing vaccines or extracts of the gonococcus.

"It is with great pleasure that we express our thanks and obligation to Dr. Albert E. Steele for preparing the vaccines and the extracts which we used, and to Dr. Hugh Cabot, as well as to many other members of the staff of the Massachusetts General Hospital, for the opportunity to study their patients."

An Easy Method for the Cultivation of the Gonococcus. G. F. Clark, U. S. N.[14] Clark uses Thalmann's medium and human blood serum. His technic follows: "Five hundred grams of lean, finely minced beef are placed in 1000 c.c. of distilled water and allowed to stand over night in an ice box. It is then filtered and the filtrate made up to 1000 c.c. with distilled water. To 100 c.c. of the beef juice add 1½ grams of agar and boil for fifteen minutes. Then add 2 grams of glucose and bring the reaction to plus 0.6 by addition of NaOH. Tube, sterilize, slant and incubate over night. No peptone or salt is required. To each tube of the medium add 4 to 5 drops of fresh, sterile human blood-serum. After washing the glans penis with alcohol and wiping off any secretion at the meatus, a drop or two of the pus is expressed from the meatus and inoculated on the medium. It is best to incline the test-tube prior to inoculation, so that the serum will flow over the entire surface. The pus should be evenly spread. In sixteen hours the colonies of gonococci can be readily seen as small white points. Toward the bottom of the tube the colonies are larger, sometimes almost as large as staphylococci when grown in ordinary mediums."

Complement Fixation Test. Schwartz and McNeil.[15] The authors state their belief that the complement fixation test is simpler than that of isolation of the germ in culture and they think the possibilities of error are less. They detail the following figures:—

A positive reaction in 31.4% of cases, clinically post-gonorrheal; a positive reaction in 54.8% of 62 patients, infected within 3 years; a positive reaction in 13.2% of 165 patients, clinically cured after three months.

EXCRETION OF FORMALDEHYDE.

An Experimental Study of the Antiseptic Value in the Urine of the Internal Use of Hexamethylenamin. Hinman.[16] "Hinman finds that hexamethylenamin is easily converted into formaldehyde in an acid medium but not in an alkaline one. The amount of excretion in the urine is influenced by the size and frequency of the dose and the changes that occur in the acid contents of the stomach. Disease of the kidney has no influence on the formaldehyde content of the urine. Doses smaller than fifteen grains three times a day cannot be expected to produce much antiseptic action.

Excretion of Formalin in the Urine and Inquiry into the Accuracy of Burnam's Test.

Smith.[17] In our last report, published in this JOURNAL (January 2, 1913) mention is made of the work of Burnam and L'Esperance. In the paper under consideration Smith discusses Burnam's work, and from a study of 213 specimens of urine obtained from fifty persons, draws the following conclusions:—

"1. Burnam's test for formaldehyde in urine is definitely positive when this substance is present in the strength of 1 part in 40,000 or more.

"2. The urine should be examined as soon as possible after it has been voided. A negative test at one time does not prove that formaldehyde is never liberated.

"3. From the evidence at hand, we believe that formaldehyde is liberated from the hexamethylenamin by the acids of the urine, not by a specific function of the renal epithelium.

"4. This process may take place in the kidney, but is continued in the bladder.

"5. Litmus paper, as an indicator of the true acidity of the urine, was unreliable in about 25% of the cases examined.

"6. The degree of acidity of urine, as measured in terms of its hydrogen ion concentration, showed in our cases a constant relation to its power to set free formaldehyde. The higher the acidity, the greater was this power.

"7. The requisite amount of acidity, which is not great, is present in the majority of normal urines, and can be secured in almost all cases by the use of boric acid or sodium acid phosphate.

"8. The writer disagrees with the statements of Burnam and L'Esperance that only 50 to 60% of individuals break up urotropin. Examination of 213 specimens from 50 individuals showed that only in the urine of one case was formaldehyde never found."

VALUE OF NEPHRECTOMY IN CASES OF UNILATERAL RENAL TUBERCULOSIS.

By Dr. J. Z. Barrie, of Lyons, France, 1912. (A Rey, 4 Rue Gentil, Lyons.)

This very thorough and interesting monograph rests for its material upon a number of patients selected from the clinical records of one of the most careful analyzers of clinical material in France, Dr. Rafin, which embraces a considerable number of patients whose records are complete both as to the conditions preceding operation and to the late results of the nephrectomies.

The reporter of these observations precedes them by saying that the diagnosis of unilateral renal tuberculosis was most carefully tested before operation and also afterward, and divides the work that he details for the further aspects of the cases as follows:—

What is the duration of renal tuberculosis when no operation is done?

Then the question of spontaneous cure of renal tuberculosis is considered in the light of hitherto published evidence. In a third chapter the question is considered, "Does the disease in one kidney threaten involvement of its fellow organ?" And in connection with this question the results of the study of the immediate and late results of nephrectomy in cases of unilateral renal tuberculosis are considered.

Finally, the comparison of the advantages gained by the removal of the focus of tuberculous disease is made with the disadvantages of leaving such a focus undisturbed by surgical intervention. In 91 cases observed and whose histories until death were known, death took place at the following times after the beginning of the malady in the cases in which no operations were done.

In the first year death occurred in 19.
In the second year death occurred in 10.
In the third year death occurred in 15.
In the fourth year death occurred in 8.
In the fifth year death occurred in 7.
In the sixth year death occurred in 13.
In the seventh year death occurred in 6.
In the eighth year death occurred in 5.
In the ninth year death occurred in 2.
In the tenth year death occurred in 1.

From the tenth year to the sixteenth year there were 5 deaths.

Of the surviving patients there were 77.

Of these, 18 had had the disease for 1 year to 2 years; 19 had had the disease from 3 years to 5 years; 28 had had the disease from 6 to 10 years; and 12 for more than 10 years.

The average time of death in the cases in which the patients had died was four years and six months, and the average time of life reported in the cases in which the patients were still alive was 4 years and 9 months.

The cases are further analyzed with regard to duration of life or occurrence of death in women as compared with men and also according to the ages of the patients attacked.

The first of these analyses indicates that death comes later in the cases of women than of men.

In considering the question of spontaneous cure of renal tuberculosis, he examines the cases from two points, these are the conditions found at autopsies and carefully established clinical observations.

Data are given of cretaceous areas surrounded by fibrous capsules in the kidneys, which have been interpreted as being tuberculous processes, either healed or en route to become so in some instances, while in other cases kidneys have been found with areas of cicatricial tissue which have been variously interpreted, but concerning which there is lacking definite proof of their being end results of a tuberculous process. The general consensus of opinion is that a completely healed tuberculous process, if it occurs at all in the kidney, is of very rare occurrence, and many authorities deny the existence of such a condition.

The clinical facts are almost as rare as are those which point to the possibility of a spontaneous cure in cases of renal tuberculosis. One

instance reported by Wildbolz seems to be pretty well established and by all the known tests by which the presence or absence of the malady can be discovered.

He calls attention to the deceptive condition that may be presented in the cases in which the kidney has the ureter closed and undergoes caseous atrophy under a tuberculous process, and in which cases cured may be absolutely simulated and yet the process still be present in the shut-off kidney.

Barrie then takes up the question of the effect or the transmission of the malady from one kidney to the other. He gives statistics which seem to show that in cases in which one kidney is infected the disease is transmitted to the opposite organ in a considerable number, rather than from some extra-renal focus, and calls attention to three series of facts which indicate the involvement of the second from the first kidney infected.

Israel reports, for instance, that in the series of cases published by him there were more cases of bilateral renal tuberculosis in which the infection was confined to the kidneys than there were, or those in which there was an extra renal focus of the disease,—this in bilateral cases.

If this fact be true it would point to the greater frequency of the transmission of the infection from one kidney to its fellow than to the second kidney from any extra renal focus.

The second fact cited is that when one kidney is removed there is a decidedly lesser chance that the second one will be infected than when the two organs are allowed to remain.

In considering the question of cure in unilateral cases by means of nephrectomy the number of cases in which cure can be definitely established is as 32.0% of the whole number operated.

In five of these cases the cure has been demonstrated by testing the patients more than eight years after operation. In 32 cases the cure is established and endures from five to eight years.

Later in the report the influence of nephrectomy upon the bladder in unilateral cases is given.

Of 52 cases in which careful observations were made there were 5 in which no benefit was derived on the part of the bladder from the nephrectomy; in 43 there was a return to the normal subjective condition of the bladder promptly; in 9 it occurred slowly. With regard to the condition of the urine following nephrectomy the following statements are made:

In 35 of the cases the urine became and remained perfectly clear after the operation; in 8 others it did not.

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY.

MEETING OF THE MEDICAL SECTION JANUARY 21, 1914, AT THE BOSTON MEDICAL LIBRARY.

L. H. SPOONER, M.D., SECRETARY.

Dr. Horace D. Arnold read a paper entitled,

SOME PROBLEMS IN NEPHRITIS.*

DISCUSSION.

DR. H. A. CHRISTIAN: We are indebted to Dr. Arnold for his presentation of this important subject, presented largely by means of the review of a few very carefully studied cases, some observed for a long time. I would like to emphasize at this time the importance of such observations on the part of practitioners. Chronic nephritis is a common disease, so all have the opportunity of observing it. It is a disease of long duration, consequently the practitioner has a distinct advantage over the hospital physician in its study. Being a disease of long duration, it is the private patient, who is followed year in and year out by the general practitioner, and not the hospital patient, who comes for a brief time and is frequently then lost sight of, who furnishes the best opportunity for study. Furthermore, it is important that the patient under investigation should be intelligent and well to do, because intelligent coöperation on the part of the patient is necessary and because it is only among the well to do that the opportunity is afforded for continued use of special diets. So the well-to-do individual of intelligence observed for a long time is almost a requisite for such a study. At this time I wish to emphasize the very great importance to all of us of following these patients through the course of their disease, and when they die, of securing autopsies in order to know the exact condition in the kidney about which the physician has been speculating over a period often of years. Only a very few carefully observed cases of this nature have been recorded with autopsy findings.

Dr. Arnold has presented to you an hypothesis as to the etiology of nephritis and as to the cause of hypertension in chronic nephritis. I am quite sure that he has presented this as an hypothesis to serve as a guide to investigation rather than as a demonstrated fact. Such an hypothesis is of value, because if observation proves it to be correct we thereby have secured information as to definite facts. If observation proves it incorrect, it has helped because it has led to a study which has in the end provided us with facts, notwithstanding these facts

* See page 601.

may be contrary to the hypothesis with which we started.

Personally I do not feel that there is any necessarily close relation between high protein intake and hypertension. In the hospital, looking over the records of bood-pressure, I repeatedly see in some cases the blood-pressure fall, in others rise, when all of the patients are essentially under the same conditions of rest in bed, and diet, have, so far as we can make out, essentially the same pathological condition. These changes in blood-pressure take place without our being able to assign any definite cause. Furthermore, I have not infrequently observed the blood-pressure to fall while the non-proteid nitrogen of the blood rose. Recently we had under observation a case in which the blood-pressure was 240 millimeters of mercury with 96 milligrams of non-proteid nitrogen per 100 c.c. of blood. As the non-proteid nitrogen in the blood rose to 129 milligrams, the blood-pressure fell to 220, and when it further rose to 330 and 347 milligrams, the blood-pressure had fallen to 180. Furthermore, we not infrequently see very high blood-pressures without any evidence of the accumulation of non-proteid nitrogen in the blood.

Studying the ability of the kidney to excrete various substances, we find in some cases with high blood-pressure and with evidences of chronic nephritis that the individual is able to excrete nitrogen well and salt poorly. Other cases are able to excrete salt well and nitrogen poorly. Still other cases excrete both salt and nitrogen well, while a fourth group excrete neither salt nor nitrogen well. All of these cases have hypertension. Whatever the cause of the hypertension, it would seem that there are different types of cases on this group. It might be very helpful in getting at a proper dietary treatment for such cases to know these facts in advance and to model a diet in accordance with such observations. In the hospital quite easily such determinations can be made in relatively short time. Then a diet can be planned, but that diet must be continued for a long time before any definite conclusions can be drawn from its use. In this sense it would seem necessary that both the hospital physician and the general practitioner should share in the investigation and each would have a very definite part in the study.

DR. R. FITZ: Dr. Arnold has described striking results in the dietetic treatment of chronic nephritis. But to make any form of treatment most efficacious, a positive and accurate diagnosis of the existing lesion must be made as early as possible. Dr. Folin has pointed out that the different parts of the kidney have selective excretory functions, and Dr. Arnold has outlined tests which may be made to study various renal excretions. The basis for these tests is experimental and theoretical, and the interpretation of the results obtained has not been controlled in a sufficiently large number of cases to establish their significance from an anatomical-pathological point of view. But enough clinical evidence has accumulated to prove that their use is of real worth in the early diagnosis of kidney disease.

Every clinician is familiar with patients who consult him for indefinite cardio-vascular symptoms. Physical examination shows a slight cardiac hypertrophy. The blood-pressure may be increased. The urine is normal by ordinary tests. In this class of cases it is essential to discover the existence of a nephritis. It is in this group of cases that the more delicate tests for renal function are of greatest importance.

In such patients the phthalein test is usually normal, while the rest-nitrogen of the blood does not afford positive information of a renal lesion, since it has not accumulated. But the excretion of lactose, nitrogen, salt, water and iodide may definitely prove or exclude abnormal function on the part of the kidney, and if observed repeatedly, makes it possible to follow the progression of the disease before there are any outspoken clinical signs of its existence. Thus it must be emphasized that the finer tests for renal function are valuable in the diagnosis and prognosis of kidney disease as well as in serving as a guide to rational dietetic treatment.

DR. OTTO FOLIN: From an extended series of observations made on patients at the Long Island Hospital we believe that there is no tangible relationship between the blood-pressure and the accumulation of nitrogenous waste products in the blood in nephritis. The accumulation of such waste products can be modified, increased or diminished within very wide limits by the use of high and low nitrogen diets, but we have failed to find corresponding variations in the blood-pressure.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

MEETING OF WEDNESDAY, FEBRUARY 4, 1914, 8 P. M.

The President, DR. JAMES C. WILSON, in the chair.

DR. WILLIAM S. NEWCOMET read a paper on,

ONE HUNDRED CASES OF MALIGNANT DISEASE TREATED WITH RADIUM.

DISCUSSION.

DR. EDWARD A. SHUMWAY: The last patient shown by Dr. Newcomet has been under my observation since 1900, when I operated upon him for convergent squint. The results of the operation were excellent and he was comfortable until 1911 when he developed severe headache associated with vomiting and staggering toward the left side. In March, 1912, Dr. Frazier operated, evacuating and removing the wall of a cyst the size of a walnut found on the upper surface of the left cerebellum. The symptoms were entirely relieved but there was a recurrence of symptoms in the spring of 1913. In September Dr. Frazier did a second operation and found a solid growth in the cerebellum on the left side which proved to be a glioma. The case was considered inoperable, but upon the father demanding that something be done, the boy was referred to Dr. Newcomet. The result as seen now is gratifying. It is possible that the improved condition of the optic nerve head may be the result of the second operation, which, however, did not improve the general symptoms. Whether the improvement be temporary remains to be seen. The case, however, is well worthy of report.

DR. CHARLES H. FRAZIER: It is evident from the reports of Dr. Shumway and Dr. Newcomet that the application of radium has had a very positive influ-

ence upon the growth. We have had several cases, however, in which improvement following a simple decompressive operation in conditions precisely similar to this case, has continued over a period of at least three years. Regarding the use of radium in tumors of the brain Dr. Robert Abbe of New York and I have discussed the feasibility of using radium directly at the time of operation, not only in brain tumors generally, but possibly in lesions of the pituitary body, and we have under observation two cases in which such procedure may be employed.

DR. GEORGE E. DE SCHWEINITZ: It seems to me that there is a certain use which radium has, even if it is unable to check the progress of a growth, namely, the alleviation of pain. We may not always hope to remove the growth, but even if there is a relief of pain, the application of radium is abundantly justified. Of its value in deep-seated growths I can express no opinion, because I have not had any personal experience. Dr. Newcomet is to be congratulated on the conservative attitude which he has assumed.

DR. JAY F. SCHAMBERG: Dr. Newcomet should be congratulated upon the encouraging results shown in the patients exhibited. Likewise he should be commended for his conservatism. I feel that we ought to maintain a feeling of hopeful expectancy regarding the results of radium treatment. We are in an experimental period. The most hopeful cases Dr. Newcomet shows are those of pronounced influence upon metastatic lesions in the lymphatic channels. It is fortunate that we have had presented this evening a paper which differs in tone from the extravagant utterances which have appeared in the public press within recent months.

DR. M. B. HARTZELL: Dr. Newcomet is to be congratulated upon his rational conservatism. The most we can say about radium is that it is a hopeful remedy, and that, when we have learned more about it, perhaps we shall discover that we have a remedy for a certain class of malignant growths.

DR. ALFRED GORDON: It would be one of the greatest acquisitions in medicine if radium could be applied to tumors of the brain. When Dr. Abbe came a short time ago before the College it occurred to me to ask him why this agent should not be tried in tumors of the brain, which are practically all hopeless cases. He seemed somewhat surprised by this question and said he would make an effort to make such application of this agent. Literature gives instances of the successful use of radium in some neurological conditions, such as obstinate cases of sciatica. It has also been employed in syringomyelia and in progressive muscular atrophy.

DR. A. B. HIRSH: In view of the expensive charges being made for the radium emanation bearing waters for internal administration, it should be remembered that the Department of Agriculture at Washington has issued a caution that these waters lose their medicinal effect within a few hours after leaving the source of supply.

DR. JOHN A. MCGLINN: I have had no experience with radium, except one case which I sent to Dr. Newcomet. It seems to me that in these cases of inoperable cancer of the cervix radium has its greatest field, if results equal those in the case shown tonight.

DR. NEWCOMET, closing: With reference to the direct application to the brain case referred to by Dr. Frazier, it seems hardly necessary to open the head to make these applications with the radium, as the "crossfire" should answer and give us as perfect result. The case presented tonight gives an example of this method and while decidedly improved, hasty conclusions must be withheld. It must be admitted that sarcomas are always most irregular in their course, and glioma is of sarcoma type. The cases of spontaneous cure have usually been sarcoma. The ideal method of using radioactivity is to employ the emanations of radium. Emanation waters must be used soon after derivation from their source. Where you have a large supply of radium the emanation should be taken off for use and the radium kept in stock.

THE CURE AT VITTEL.

DR. WILLIAM J. TAYLOR: Vittel is in northeastern France, in the Vosges, in a wide valley with an elevation of 1100 feet. The waters may be classed as mild alkaline bicarbonated, sulphated waters, non-chloride bearing, the most pronounced characteristic being the almost total absence of chloride of sodium. Their mineralization is sufficient but not excessive, and they have not the inconvenience of waters highly charged with sulphate of lime, nor the dangers of waters too strongly alkaline. The really active principles are the sulphates, carbonates and chlorides of magnesia, soda and potash, and to some extent the bicarbonates. The waters of Vittel are readily absorbed and have not the tendency to liberate free carbonic acid, and can be used with great freedom as a table water. The absence of sodium chloride renders them of the greatest value in all kidney troubles, in arterial degeneration, as well as in many diseases of the heart, and in all neurasthenias consequent upon toxemias of every sort. The Vittel treatment is primarily that by diuresis. The dosage must be carefully adapted to different individuals and diseases. Massage of some sort is essential. One form given,—massage under water,—is simply massage and movements of all the joints while a spray of hot water is playing over the whole body. I believe that the greatest efficacy of these waters is in cases of excessive uric acid and other waste products or toxemias and renal calculosis. The action in lowering blood-pressure is most marked by diminishing the viscosity of the blood. I regard this method of diuresis by drinking large quantities of the moderately mineralized sodium chloride free water as far superior to treatment by baths, sweating and the heavy drinking of actively purgative and highly mineralized waters. Contraindications to the treatment are very low blood-pressure, grave valvular cardiac disease and profound anemias. In certain juvenile epilepsies, particularly those with digestive disturbance and faulty elimination, I am told that the use of the waters is of the greatest value in diminishing the number of seizures, and in a few cases they seemed to be of lasting benefit.

DISCUSSION.

DR. WILLIAM S. NEWCOMET: Dr. Taylor mentioned the fact that possibly some of the value of these waters was due to the radioactivity that they possessed and which during transportation was lost, this accounting for the results obtained at the springs. It might be mentioned that most of these waters are radioactive, but more especially those that come from deep wells.

Dr. H. B. Allyn: I have not had the pleasure of visiting Vittel, but for some years have been using here the waters for gout, gouty conditions, neuralgias and the general neurasthenic states accompanying gout, and for gravel, and I have found them the best of any heretofore employed for these purposes.

Dr. James M. Anders: I have prescribed this water in selected cases and have found it to be an efficient diuretic. It contains no chloride of sodium, and the diet prescribed in the course of treatment is a salt free or salt poor diet, which two facts, in a large measure, explain the efficacy of the water, both as a diuretic and eliminator of poisonous wastes. Certain elements of the life at Vittel, —restricted diet, walks, freedom from care and responsibility must be given weight These waters are not in the slightest degree laxative, nor to any extent diaphoretic. Treatment, therefore, is based largely upon the diuretic action of the water. The results, it seems to me, corroborate in a striking manner the generally accepted opinion that the kidneys are the principal eliminating channels of the body.

Dr. Taylor, closing: I have nothing to add, except that Vittel is now becoming very popular, but is patronized almost entirely by French speaking people. During my stay I did not see half a dozen Americans or fifty English people.

Dr. Alfred Gordon read a paper on,

CEREBROSPINAL FLUID AND A SPECIAL METHOD OF TREATMENT OF ESSENTIAL EPILEPSY.

The value of lumbar puncture and the importance of study of cerebro-spinal fluid for diagnostic and therapeutic purposes are described and mention made of toxic products usually present in the blood and in the cerebro-spinal fluid in epilepsies. Attention is called to the work of Geni and Donath with reference to the toxicity of blood serum in epileptic individuals. It is then estimated that if the cerebro-spinal fluid of one epileptic patient could be injected in another epileptic patient, thus bringing into the economy two opposing toxins, gratifying results might be secured. Four patients were subjected to the treatment in a period of ten months. There has been decided diminution in number of attacks and in severity, with general improvement in mentality and all functions. The treatment is shown to be far superior to any other. Rules are outlined for future investigation in this field of work.

Dr. Morris J. Lewis: Dr. Gordon does not mention whether in any of the cases the Wassermann reaction was present or not. In a rather large experience I have found this reaction present in quite a large proportion of cases, especially in cases developing after puberty. I would hesitate about using spinal fluid in the manner mentioned, and especially, without knowing most definitely that there was no communicable disease present.

Dr. Gordon, closing: Unquestionable hesitation should be felt in any new treatment. I did not introduce the fluid into the spinal cord, but subcutaneously. I simply take this opportunity to present to the profession the favorable results so far obtained, which, so far as I know, have not been gained by any other method. The Wassermann test was made and found negative.

Book Reviews.

A Text-Book of Histology. By Frederick R. Bailey, A.M., M.D., Fourth revised edition. pp. xviii+644. Figs. 384. New York: William Wood and Company. 1913.

In the new edition of Bailey's Histology "the text has been thoroughly revised and some parts of it rewritten"; fifty-five pages and thirty figures have been added, but it has seemed unwise to alter the general plan of so successful a text-book. This plan consists in presenting a clear and simple account of the well-known facts of histology. Indeed, reference is frequently made to the sharply contended issues of the day, but the author usually writes of them with the fairness and unconcern of a noncombatant and consigns them to small type. The development of the various tissues and organs is also lightly treated, usually in the form of postscripts to the accounts of the corresponding structures in the adult. What to do with the nervous system has long been a puzzling question for the writers of histological text-books. Stöhr, for example, deals with it very briefly and refers his readers to special treatises. Bailey's Histology, however, includes a special treatise of 132 pages, written and revised by Dr. O. S. Strong, in which the nuclei and fiber-tracts are concisely described. This thorough treatment of the central nervous system is perhaps the most notable feature of the book.

Among the illustrations one sees many old familiar figures, since two-thirds of them have been gathered from other sources, including many from the standard text-books. As stated in the preface,—"The uselessness of redrawing perfectly satisfactory illustrations has led the writer to borrow freely." His indebtedness is correspondingly great, but the ignominy of appearing like Aesop's daw in peacock plumes has been avoided by frankly acknowledging the source of every figure. Both figures and text have been well printed, and the volume is attractive, though somewhat heavy.

Medical Jurisprudence from the Judicial Standpoint. By W. Ramsay Smith, M.D., C.M., D.Sc., F.R.S. (Edin.). London: Stevens and Sons, Limited. 1913.

The monograph aims to view "the principles and practise of medical jurisprudence from the point of view of the court, the bench, and the judge." Such an exposition by a physician argues unusual and intimate familiarity with the law, and this indeed the author appears to possess. The English common law is the basis of the work; but its colonial and American

modifications, together with the civil law, are also considered. The subject is illustrated with representative cases from actual experience. The volume should be of value to any physician who is in any way to be involved in legal procedure.

Anatomy and Physiology. A Text-Book for Nurses. By JOHN FORSYTH LITTLE, M.D. Philadelphia and New York: Lea and Febiger 1914.

This excellent first-year text-book for nurses is a useful contribution to the teacher's working material. It is well arranged, and is illustrated with 147 engravings and 4 plates, many of them taken from Gray's Anatomy. There is a list of appropriate questions at the end of each chapter; and at the end of the book are tables of weights and measures and a useful glossary. The volume is published in the Nurses' Textbook Series.

Manual of Surgery. By ALEXIS THOMSON, Professor of Surgery, University of Edinburgh; and Alexander Miles, surgeon Edinburgh Royal Infirmary. Volume Third. Second edition. With 255 illustrations. Edinburgh, Glasgow, and London: Henry Frowde and Hodder and Stoughton. 1913.

This third volume, on operative surgery, was first added to the fourth edition of this standard Scottish work, and was reviewed in the issue of the JOURNAL for Nov. 21, 1912 (Vol. clxvii, p. 738). In this second edition of the new volume, the Basle anatomic nomenclature has been adopted, the older terminology being also retained in brackets and the equivalents included in the index. The number of illustrations has been increased from 220 to 255, and the total of pages from 565 to 620. A chapter has been added on arterial suture. The volume securely maintains the immediate position of acceptance which it found on first publication.

Tropical Medicine and Hygiene. By C. W. DANIELS, M.B. Cantab., F.R.C.P., Lond. In three parts, with colored and other illustrations. Part I. Diseases Due to Protozoa. Second edition. New York: William Wood and Company. 1913.

The first edition of this volume, by Daniels and Wilkinson, was reviewed in the issue of the JOURNAL for June 2, 1910 (Vol. clxii, p. 755). In this second edition, from which the name of the junior author has disappeared, an alteration has been made in the arrangement of the material whereby the amount of repetition is diminished. The subjects of prophylaxis, treatment, and nursing are more extensively considered in connection with each disease. The terminal appendices have been reduced from five to three by the withdrawal of the classification of the *diptera*, but the total number of pages is increased from 264 to 277. The two colored plates have been improved and transferred from the end of the book to the front; and the number of figures in the text has been increased from 62 to 73, and an introductory list of illustrations added. The book should easily maintain its position of value in the literature of tropic diseases.

Principles of Surgery. By W. A. BRYAN, A.M., M.D., professor of surgery and clinical surgery at Vanderbilt University, Nashville, Tennessee. Original illustrations. Philadelphia and London: W. B. Saunders Company. 1913.

A book of seven hundred pages, well printed, and adequately illustrated with pictures and microphotographs, limiting itself entirely to "Principles of Surgery"; eliminating, therefore, operative technic and condensing treatment into brief paragraphs, sometimes sentences, which are to be found at the end of individual chapters. It is thus possible for a man of Dr. Bryan's experience and knowledge to condense a large amount of information within a small compass. It is the new example of the reaction against enormous systems of surgery which have been recently so common.

The reviewer desires to recommend this book enthusiastically. It is one of the most successful examples of condensation which we have seen in years. It is comprehensive, and yet eliminates everything that is not essential. Its brief passages on treatment are admirable in tone and in accordance with the most advanced views. For instance, anthrax. It has been shown that the means formerly employed, of excision or cauterization, rendered the dislodgment of the bacteria from the malignant pustule much more probable than if no such interference had been made. Even so insignificant trauma as may be done by hypodermic injections or attempting to lift the eschar, are interdicted. In other words, eliminating operative treatment.

The chapters on tumors and cysts constitute about one-third of the book and again attract the reader by a combination of brevity and thoroughness. The writer's purpose has been to put the fundamental facts before the student and the physician in a simple and logical way, and thereby to lay a foundation upon which an intelligent understanding of the immense details of practical work may be built.

The book may be studied with benefit by every man who has had two years of medical training.

THE BOSTON

Medical and Surgical Journal

THURSDAY, APRIL 16, 1914.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States. $6.56 per year for all foreign countries belonging to the Postal Union.*

Papers for publication, and all other communications for the Editorial Department, should be sent to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston. All orders for reprints must be sent in writing to the Editor on or before the day of publication.

The Journal will furnish 100 reprints free, if requested in writing.

All letters containing business communications, or referring to the publication, subscription or advertising department of the Journal, should be addressed to the undersigned.

Remittances should be made by money order, draft or registered letter payable to

W. M. LEONARD,

101 TREMONT STREET, BOSTON, MASS.

GENERAL PARESIS AND THE DIFFICULTIES IN ITS TREATMENT.

THE recent advances which have been made in our knowledge of syphilis have surely come to us in quick succession. Our progress in the knowledge of malaria and trypanosomiasis should be a source of great optimism for us. Our advances in the acute contagious and infectious diseases have been noteworthy, but in few diseases have we had such rapid progress as in syphilis, and particularly in syphilis of the nervous system. First we have Schaudinn, not a physician, but a zoologist, discovering the spirocheta pallida, latterly and more properly called the treponema pallida, which is now generally acknowledged to be the causative organism of syphilis. It was not long before this was followed by the Wassermann reaction and its modifications with the blood serum, as a laboratory test for past or present, latent or active syphilis. Then we have the application of chemical, serological, and cytological methods to the spinal fluid for the diagnosis, prognosis and treatment in acute and chronic infectious conditions of the central nervous system. The investigation of the cerebrospinal fluid now consists of the Wassermann reaction, the tests,—Noguchi, Nonne-Appelt and others,—for increased globulin, and the quantitative and qualitative cell count, especially pleocytosis and lymphocytosis. Recently the Lange gold solution test has been added to our laboratory armamentarium.

In pathology, too, we have been making great headway. This applies particularly to the pathology of general paresis and locomotor ataxia, the so-called para- or metasyphilitic diseases. Ordinarily cerebrospinal syphilis presents a pathological lesion which is confined mainly to the blood-vessels and meninges, with the well-known endarteritis of Heubner, with gummatous exudation and lymphocytic infiltration, whereas, in the so-called parasyphilitic diseases, namely, general paresis and locomotor ataxia, we find the changes in the neurones or nerve cells. The first-named condition, cerebrospinal syphilis, is, accordingly, essentially a lesion of the interstitial connective tissue. The second group, paresis and tabes, are, on the other hand, essentially lesions of the parenchymatous tissues of the nervous system. It was thought, for this reason, that the two contrasting conditions could not be due to exactly the same cause acting in precisely the same way, but that, although tabes and paresis showed a decided relationship to syphilis, they were not caused directly by the spirocheta pallida, but were due, in some unknown way, to toxins acting upon the nerve cells after the spirochetes had spent their force, after the fashion, we may say, of neuritis or paralysis following in the wake of diphtheria.

Noguchi and Moore[1] have, however, recently found the spirochete in the brains of twelve out of seventy patients who had had frank general paresis, as proved by the clinical, laboratory and pathological findings. Later Noguchi[2] reported the finding of the spirochete in forty-eight brains among two hundred of general paresis, and in one spinal cord out of twelve of locomotor ataxia. Noguchi also infected rabbits directly with the tissue from general paretics and produced a perfectly typical luetic lesion in the testicle of the rabbits so infected, and was able to recover the spirochetes from these lesions.[3] The finding of the spirochete in the brain of paretics has since been confirmed by others, notably Marinesco. Forster and Thomasczewski[4] resorted to the method of brain puncture in the living general paretic, aspirated cortical substance from the brain and demonstrated the presence of living spirochetae pallidae in the cortical tissue from the brains of these living paretics. From the experimental

[4] *Deutsche Med. Wochenschrift*, 1913, Vol. xxxix, No. 26.

investigations and findings of such scientific and reliable workers in the field of experimental medicine we may conclude, at least in the case of general paresis, that syphilis is the direct causative factor in the production of this strange disease.

The findings in paresis show that the organism is imbedded deep within the tissues, far away from the blood vessels, and practically in direct contact with the nerve cells themselves. There is, further, an accumulation or infiltration of lymphocytes about the blood vessels, especially in the perivascular lymphatic channels. The reason why the spirochete has not been found in the past seems to be because the examination was directed mainly to the regions of the blood vessels, and the examinations were not as conscientious, prolonged and intensive as they should be. Moreover, in paresis the spirochetes are difficult to see, even with the modern staining methods.

The reason for the resistance of paresis to treatment by ordinary anti-syphilitic methods is not easy to explain, but recent study discloses the following facts: The spirochetes are so deep in the tissues that they are not easy to get at through the blood stream, which difficulty is further enhanced by the infiltration of the adventitial spaces, the so-called perivascular lymphatic spaces, with leucocytic invasion, and hence an interference with diffusion of spirocheticidal poison (mercury, arsenic, salvarsan). It is particularly for this reason that the results produced by mercury and salvarsan, intramuscularly or intravenously, have not been encouraging in paresis. It is also supposed that in paresis we may have a different kind of organism, having from the very beginning a different affinity for nervous tissue or a greater resistance, or the same species of organism may have, as we find in ordinary cerebrospinal syphilis, for some reason or other invaded the deeper structures with its destructive effects upon the parenchymatous nervous tissues and become unduly resistant.

The problem which here presented itself was how to reach the spirochetes buried deep within the brain substance and apparently but little accessible by way of the blood stream. Certain observations having shown that salvarsan, after being administered intravenously, cannot be recovered in the cerebrospinal fluid withdrawn by means of lumbar puncture, we were justified in concluding that the possible spirochetes in the cerebrospinal fluid were not reached by the salvarsan. It was logical, therefore, to expect that when this drug, in some way or other, is injected directly into the subdural space, more direct contact with the spirochetes might be obtained. It was found, however, that the drug salvarsan, when diluted with salt solution and injected into the spinal canal (subdural space), was injurious and capable of doing serious injury to the nerve structures. It may be noted here that recently (March, 1914) it was reported that there had been seven deaths from neosalvarsan in Los Angeles, California. Investigation disclosed the fact that the drug neosalvarsan had been mixed with salt solution and given intraspinously. Swift and Ellis, however, overcome these difficulties by using the serum taken from other syphilitic patients or from the same patient, the latter having received one hour previously an intravenous injection of salvarsan or neosalvarsan.[5] Thus hetero- or autosalvarsanized or neosalvarsanized serum was being employed, this being further diluted with normal saline solution. Lately certain modifications, such as the intraspinous injection of undiluted auto-salvarsanized serum, have been tried by various workers in the field of intraspinal therapy.

For the technic and results of this method of treatment the reader is referred to the original articles by Swift and Ellis and others.[6]

The lesson to be learned from a consideration of the facts here enumerated is this: We should do our utmost to attempt to make an early diagnosis in general paresis, by both clinical and laboratory examination. As soon as the diagnosis is made treatment should be instituted. This should be vigorous anti-syphilitic treatment, mercury and potassium iodide, and salvarsan or neosalvarsan, intravenously and intraspinously, being employed. The case should be watched and checked up by repeated examinations clinically and in the laboratory. The Wassermann reaction in the cerebrospinal fluid and the cell count are especially important guides as to prognosis and the results of our therapeutic efforts. Under these conditions it is at least possible that the results may be more favorable than hitherto reported.

MEDICAL LEGISLATION. SUPPRESSION OF ILLEGAL TRAFFIC IN HABIT-FORMING DRUGS.

THERE are at present pending, before both the national congress and the legislature of this Commonwealth, bills aiming to suppress the illegal sale of habit-forming drugs. The extent to which such drugs, notably morphia and cocaine, are consumed by habitués constitutes a serious menace to the health as well as the morals of the community, and any legislative attempt to control their sale is therefore important and deserving of medical attention.

Of the two measures of this type now under consideration by the Massachusetts General Court, one prohibits druggists from filling any prescription containing a habit-forming drug, the other makes it a criminal offence to dispense such drugs for other than legitimate medicinal use. The first is aimed at those habitués who, having somehow obtained a physician's prescription for morphia or cocaine, continue to employ it indefinitely as a permanent means of securing the drug. The second is aimed at a limited, but unfortunately existent, class of irregular, self-styled, misguided practitioners, who are willing to issue such prescriptions to enable habitués to obtain drugs illegitimately. It seems that these are both desirable measures and should be enacted into law.

The measure on this subject now pending before the national congress is the so-called "Harrison Anti-Narcotic Bill." The provisions of this bill may essentially be summarized as follows:—

Sect 1. It shall be unlawful for any person to produce, import, manufacture, compound, deal in, dispense, sell, distribute, or give away any of the aforesaid drugs or articles (preparations of opium or coca, and hypodermic syringes) without having registered and paid the special tax provided for in this section.

Sect. 2. It shall be unlawful for any person to sell, barter, exchange, or give away any of the aforesaid drugs or articles except in pursuance of a written order of the purchaser or person to whom such article is given, on a form to be issued in blank for that purpose by the Commissioner of Internal Revenue.

Sect. 3. Any person who shall be registered in any internal-revenue district under the provisions of section one of this act shall, whenever required so to do by the collector of the district, render to the said collector a true and correct statement or return, verified by affidavit, setting forth the quantity of the aforesaid drugs and articles received by him in said internal-revenue district during such period immediately preceding the demand of the collector, not exceeding three months, as the said collector may fix and determine; the names of the persons from whom the said articles were received; the quantity in each instance received from each of such persons, and the date when received.

Sect. 4. It shall be unlawful for any person who shall not have registered and paid the special tax as required by section one of this act to send, ship, carry, or deliver any of the aforesaid drugs or articles from any State or Territory, the Territory of Alaska, the District of Columbia, or any insular possession.

Sect. 5. (Provides for the filing of forms and prescriptions.)

Sect. 6. The provisions of this act shall not be construed to apply to the sale, distribution, giving away, or dispensing of preparations and remedies which do not contain more than two grains of opium, or more than one-fourth of a grain of morphine, or more than one-twelfth of a grain of heroin, or more than one grain of codeine, or any salt or derivative of any of them in one fluid ounce, or, if a solid or semi-solid preparation, in one avoirdupois ounce; or to liniments, ointments or other preparations which are prepared for external use only, except liniments, ointments and other preparations, which contain cocaine or any of its salts or alpha or beta eucaine or any of their salts or any synthetic substitute for them: Provided, That such remedies and preparations are sold, distributed, given away or dispensed as medicines and not for the purpose of evading the intentions and provisions of this act: Provided, That the amount of any drug herein mentioned shall be shown upon the label of the container of such remedy or preparation. The provisions of this act shall not apply to decocainized coca leaves or preparations made therefrom, or to other preparations of coca leaves which do not contain cocaine.

Sect. 7. All laws relating to the assessment, collection, remission and refund of internal-revenue taxes, including section 3229 of the Revised Statutes of the United States, so far as applicable to and not inconsistent with the provisions of this act, are hereby extended and made applicable to the special taxes imposed by this act.

Sect. 8. It shall be unlawful for any person not registered under the provisions of this act, and who has not paid the special tax provided for by this act, to have in his possession or under his control any of the aforesaid drugs or articles; and such possession or control shall be presumptive evidence of a violation of this section, and also a violation of the provisions of section one of this act.

Sect. 9. Any person who violates or fails to comply with any of the requirements of this act shall, on conviction, be fined not more than

$2,000, or be imprisoned not more than five years, or both, in the discretion of the court.

Sect. 10. The commissioner of internal revenue, with the approval of the secretary of the treasury, is authorized to appoint such agents, deputy collectors, inspectors, chemists, assistant chemists, clerks and messengers in the field and in the Bureau of Internal Revenue in the District of Columbia as may be necessary to enforce the provisions of this act.

Sect. 11. The sum of $150,000, or so much thereof as may be necessary, shall be, and hereby is, appropriated, out of any moneys in the treasury not otherwise appropriated, for the purpose of carrying into effect the provisions of this act.

Sect. 12. Nothing contained in this act shall be construed to impair, alter, amend or repeal any of the provisions of the act of congress approved June 30, 1906, entitled "An act for preventing the manufacture, sale, or transportation of adulterated or misbranded, or poisonous or deleterious foods, drugs, medicines, and liquors and for regulating traffic therein and for other purposes" and any amendment thereof, or of the act approved February 9, 1909, entitled "An act to prohibit the importation and use of opium for other than medicinal purposes," and any amendment thereof.

The purpose of this bill is assuredly good, and in the main its provisions seem excellent. There are certain aspects, however, in which it appears questionable whether they will accomplish the end desired. In the first place Section 6 has been principally criticised, and from two opposite points of view. On the one hand, it is pointed out that this section exempts precisely the class of preparations which it is most desirable to suppress, namely, those containing small amounts of narcotic drugs from which, however, addiction may easily be acquired or maintained. On the other hand, this section is criticised because it allows only so proportionately small a dose of heroin in comparison with that of morphine.

In the second place, the Harrison bill is criticised because it does not allow a physician to supply himself with morphia or cocaine for his own dispensation in his office or on visits, without registering with the Internal Revenue Department. Such registration, it is contended, would be an inconvenience and hardship, and it is urged that manufacturers should be given more leeway in supplying registered physicians.

The first of these three objections seems by far the most important. If it be true that drug-habits are to any extent fostered by preparations of the exempted class, then these exemptions should certainly be restricted or entirely removed. The bill as a whole, however, would doubtless be beneficial, and if amended in the light of expert criticism should prove a valuable measure of national legislation towards restriction of the illegal traffic in habit-forming drugs.

VINDICATION OF ANTITYPHOID INOCULATION.

Much interest has been felt in the case of Clarence Panzer, a young man of Woodhaven, Borough of Queens, who died on April 1 after an illness of two weeks, the cause of death assigned by the attending physician being typhoid fever. As Mr. Panzer, who was a member of the 13th Regiment, New York National Guard, had, in company with other members of the regiment, been inoculated against typhoid (though a considerable time before his illness), the Health Department, although threatened with a suit for damages, very properly refused to issue a burial permit until an autopsy had been made. The case was accordingly placed in the coroner's hands, and an autopsy, made on April 2, showed conclusively that the disease to which the patient had succumbed was not typhoid fever, but malignant ulcerative endocarditis. It had also been previously known that the patient was the subject of organic heart disease. In this connection it seems appropriate to quote the following editorial from the Boston *Herald*, as a gratifying example of sound medical opinion in the lay press:

"The infallibility of typhoid vaccination as a preventive has received confirmation from an unusual New York case. A member of the coast artillery recently died of an illness diagnosed as typhoid. As he had previously been inoculated, his death attracted much attention. The anti-vaccinationists, who extend their opposition to all serums, made much of the case. They cited it in contravention of last year's army records that show but two typhoid cases, in both of which inoculation had been doubtful.

"A post-mortem examination, obtained with difficulty, showed that the New York private was not a victim of typhoid. The autopsy revealed an unusual vegetation in the heart which had caused the symptoms closely akin to those of typhoid. The error was purely one of diagnosis by the attending physician. The value of anti-typhoid vaccination remains unshaken. The incident illustrates, moreover, the duty of relatives to allow an autopsy when the interests of science demand it."

MEDICAL NOTES.

THE SOLLY TUBERCULOSIS SOCIETY.—On January 24, 1914, the physicians of Colorado Springs, particularly those interested in the care and treatment of tuberculosis, met at luncheon and formed a society for the advancement in scientific treatment and prevention of tuberculosis. The organization was named "The Solly Tuberculosis Society" in honor of the late Dr. S. Edwin Solly, of this city.

At the regular monthly meetings of the society some particular phase in the treatment of tuberculosis was presented in the form of a symposium covering all the latest writings in various modern languages.

The first regular meeting of the society was held Feb. 17, 1914. At this meeting the question of the influence of altitude and climate in the cure of tuberculosis was presented for discussion.

LONDON DEATH-RATES IN FEBRUARY.—Statistics recently published show that the total death-rate of London in February was only 14.8 per 1000 inhabitants living. Among the several districts and boroughs, the highest rate was 20.3 in Holburn, a central slum, and the lowest was 10.4 in Hampstead, an open suburb on the north.

AWARD OF FOTHERGILL MEDAL.—It is announced that the Fothergill gold medal of the London Medical Society for 1914 has been awarded to Dr. John George Adami, F.R.S., LL.D., Strathcona professor of pathology and bacteriology at McGill University, for his work on pathology and its practical application to medicine and surgery.

A MUNIFICENT BEQUEST.—It is announced from Philadelphia on April 8 that under the will of the late Dr. Louis A. Dühring, for many years professor of dermatology at the University of Pennsylvania, the university will receive approximately $1,000,000. This munificent bequest is to be divided between the general library, the university hospital, the departments of dermatology, archeology and paleontology, and the College of Physicians of Philadelphia.

TRANSMISSION OF BUBONIC PLAGUE.—Report from New Orleans, La., on April 6, states, on the authority of Dr. John Guiteras, director of sanitation for the republic of Cuba, that the recent cases of bubonic plague in Havana are believed to have been transmitted not by rats but by fleas conveyed in sacks of sugar.

A CENTENARIAN.—Edward Jones, who died on April 7 at Niles, near Youngstown, Ohio, is said to have been born in 1807. He was a Welshman and a sailor, but retired from the sea some years ago.

A VOTING CENTENARIAN.—Miss Margaret Swinbank, of Sycamore, Ill., who is said to have been born in 1813, cast her first municipal ballot at the general election on April 7. She is believed to be the senior woman voter in the United States.

ILLNESS OF THE KING OF SWEDEN.—Report from Stockholm states that King Gustave of Sweden was operated on April 9 for gastric ulcer. Gastro-enterostomy was done, and the royal patient is reported as progressing favorably.

GERMAN CONGRESS FOR INTERNAL MEDICINE.—The thirty-first German Congress for Internal Medicine will be held next week at Wiesbaden, from April 20 to 23, inclusive, under the presidency of Dr. Von Romberg, of München.

"The principal papers to be presented are: On Monday, April 20, "Nature and Treatment of Sleeplessness," the reporters of which subject are Herren Gaupp (Tübingen), Goldschneider (Berlin) and Faust (Würzburg). On the third day, Wednesday, April 22, at 10 a.m., by the desire of the president, Herr Werner (Heidelberg) will present a comprehensive address upon the radiation treatment of new growths of the internal organs, and on the fourth day, Thursday, April 23, at 11 a.m., Herr Schottmüller (Hamburg) will deliver an address on "The Treatment of Sepsis."

BUBONIC PLAGUE AND YELLOW FEVER IN ECUADOR.—Report from Panama on April 4 states that 21 deaths of yellow fever have recently occurred at Esmeraldas, Ecuador, among the federal troops who are holding that city; and that several cases of yellow fever and bubonic plague have been notified recently at Guayaquil.

A SCHOOL CLINIC AT SOUTHAMPTON.—In a recent address, Dr. R. E. Lauder, medical health officer of Southampton, England, describes the methods of school inspection there employed. In 1912, medical treatment by private physicians

was recommended for 1133 children. In only 328 cases was the advice followed. In 1913, therefore, the city established a municipal clinic and dispensary, in which common diseases of the teeth, eyes, nose, throat, ears, and skin are treated. A full-time dentist is there employed, at a salary of £300 a year. Visiting nurses investigate home conditions and follow up the pupils with instructions.

NEW JERSEY STATE HOSPITAL.—The recently published thirty-eighth annual report of the managers and officers of the New Jersey State Hospital, at Morris Plains, records the work of that institution for the year ended Oct. 31, 1913. During this period 2847 patients were under treatment, of whom 195 died and 84 were discharged as recovered. The institution is seriously overcrowded, and among its urgent needs are new and additional buildings and an incinerating and water purification plant.

BOSTON AND NEW ENGLAND.

SCARLET FEVER IN BOSTON.—Scarlet fever continues epidemic in Boston. Since last December there have been 20 deaths of the disease, and 555 cases are now under treatment.

SCARLET FEVER IN COHASSET.—Scarlet fever continues epidemic in Cohasset, Mass. Three new cases were reported last week. All the schools, churches, and the town hall and library have been closed.

GLANDERS IN BEVERLY.—Glanders is at present epizoötic among working horses in Beverly, Mass. Ten deaths from the disease have already occurred, and the local public drinking fountains have been ordered closed.

SMALLPOX ON A SPANISH STEAMER.—A case of smallpox was discovered recently in this port aboard the Spanish steamer *Inez*, recently arrived from Barcelona. The vessel was fumigated, the crew vaccinated, and the patient transferred to the quarantine hospital.

SCARLET FEVER IN BRIDGEWATER.—Scarlet fever is at present epidemic in Bridgewater, Mass., where 42 cases of the disease have already been reported. All schools have been ordered closed.

SMALLPOX IN BROCKTON.—Smallpox is at present mildly epidemic in Brockton, Mass. Three new cases of the disease were reported on April 1.

TWO LIVING BROCKTON CENTENARIANS.—Abraham Weiner, of Brockton, Mass., who is said to have been born in Odessa, Russia, on April 1, 1809, celebrated recently his supposed one hundred and fifth anniversary. He served for 25 years in the Russian Army before migrating in 1864 to the United States. He has five children.

Morris D. Shimelovitch, of Brockton, Mass., is said to have been born on Feb. 8, 1811. He is in excellent health and walks out daily.

INVESTIGATION OF DRUNKENNESS IN MASSACHUSETTS.—The recently published report of the commission, appointed in August, 1913, to investigate drunkenness in Massachusetts, records the work and recommendations of that body. A series of public hearings was held and numerous measures considered. The first part of the report is concerned with ascertaining and stating the nature and magnitude of the problem, the second with discussion of suggestions for the prevention of drunkenness. The commission makes ten specific recommendations for legislation, embodied in six proposed bills which are printed in an appendix. It believes that the method of committing persons to penal institutions for drunkenness is wrong in principle and should be abandoned.

HUNTINGTON HOSPITAL FOR CANCER RESEARCH.—The recently published first annual report of the Collis P. Huntington Memorial Hospital for Cancer Research records the work of that institution for the fiscal year ended June 30, 1913. During this period 75 in-patients and 115 out-patients were treated. The number of deaths is not stated. Various lines of research were pursued and two papers on the results have been published.

ABOLITION OF VITAL STATISTICS DIVISION.—The mayor of Boston has recently abolished the division of vital statistics in the health department of this city, thereby retiring Dr. William H. Davis, the statistician who held post as its chief.

COÖPERATIVE SUBURBAN BOARD OF HEALTH.—The Coöperative Suburban Board of Health,

which was organized on April 1, 1913, has just completed successfully the first year of its activities. It was designed to carry on the health work, either in whole or in part, of the towns of Wellesley, Belmont, Framingham, Weston, Needham, Melrose, Winchester, and Canton, Mass. By this combination, which was originally suggested by Prof. Earle B. Phelps of the Massachusetts Institute of Technology, each of the townships has secured far more extensive and efficient health supervision than would have been possible for it to maintain alone, and at an aggregate cost considerably less than that previously spent for this purpose. This first year has abundantly justified the theory of this plan of health work, which might to advantage be imitated in other rural and suburban town groups throughout the country.

Hospital Bequests.—The will of the late Eliza Callahan Cleveland, of Jamaica Plain, Mass., which was filed in probate on April 3, contains a bequest of $3000 to St. Luke's Hospital for Women, Shanghai, China.

The will of the late Elizabeth S. Hall, which was probated on April 7 at Exeter, N. H., contains a bequest of $10,000 to the building fund of the Exeter Cottage Hospital.

The will of the late Henry C. Whitcomb, which was recently filed at the Suffolk probate court, contains a bequest of $20,000 to the Home for Aged Couples, Boston.

The will of the late Frank Wood, of Ashmont, Mass., which was filed recently at the Suffolk registry of probate, creates a trust for the establishment in Dorchester, Mass., of a home for convalescents and incurables. For this purpose the testator gives 40 acres of land and $50,000.

Cases of Infectious Diseases reported to the Boston Board of Health for the week ending April 7, 1914: Diphtheria, 54; scarlatina, 147, of which 13 were non-residents; typhoid fever, 7, of which 1 was non-resident; measles, 86; tuberculosis, 38, of which 1 was non-resident.

The death-rate of the reported deaths for the week was 17.15.

NEW YORK NOTES.

Opening of Dispensary, Syracuse Medical College.—The Syracuse University Medical College celebrated the opening of the new Dispensary March 30, 1914. During the afternoon the building was open for inspection. The building has specially designed rooms to accommodate the following clinics: On the first floor, obstetrics and gynecology, pediatrics, genito-urinary diseases, orthopedics, and tuberculosis, with the pharmacy and offices for clerks, medical superintendent and staff. On the second floor, general surgery, proctology, nose, throat and ear, dermatology and syphilis, internal medicine, psychiatry and neurology, and ophthalmology. In the basement are the x-ray room, an orthopedic shop, a milk-distributing station and the manufacturing pharmacy. The third floor is occupied by the laboratories for chemical and microscopical diagnosis, bacteriology, and research work. A small laboratory for instant use is provided with each large clinic. The furniture and equipment is of the latest model. In the evening a public meeting was held at which Chancellor Day formally presented the use of the building and equipment to the Syracuse Free Dispensary Association, which will continue the conduct of the Dispensary as a charity, while vesting in the faculty of the College of Medicine the organization and administration of the medical and surgical service. The address of the evening was made by Dr. Richard C. Cabot of the Harvard Medical School, who with his characteristic forcefulness impressed upon the audience the importance of dispensary work and of the great advances in medical practice which would be gained by team work.

Reorganization of Presbyterian Hospital.—At a meeting of the trustees of Columbia University, held on April 6, it was announced that the Presbyterian Hospital, which is in alliance with the medical department of the university, had so reorganized its administrative work as to provide for single responsibility for both medical and surgical services. In accordance with this plan, Dr. Theodore Janeway, Bard professor of the practice of medicine in the College of Physicians and Surgeons, has been appointed medical director of the hospital, and Dr. George E. Brewer, surgical director. The pathological department of the hospital will be under the direction of Dr. William G. MacCallum, professor of pathology. At this meeting it was also announced that a gift of $2,000, for surgical research, had been received from an anonymous donor.

Death-Rate for Week Ending April 4, 1914.—There were 1612 deaths and a death-rate of

15.06 per 100 of the population reported the past week as against 1512 deaths and a rate of 14.68 for the corresponding week of 1913, an increase in the absolute number of deaths of 100 and in the rate of .36 of a point, equivalent to a relative increase of 39 deaths. The following causes showed a decreased mortality: Measles, scarlet fever, cerebro-spinal meningitis, diarrheal diseases under five years of age, influenza, bronchitis, broncho-pneumonia, pulmonary tuberculosis, Bright's disease and nephritis; the mortality from whooping cough and typhoid fever was the same as that of last year. The following causes showed an increased mortality: Diphtheria and croup, digestive diseases other than diarrhea, organic heart disease, lobar pneumonia, diseases of nervous system, violence and all other causes. The mortality of infants under one year of age showed an increase of 27 deaths, between one and five years a decrease of 38 deaths, between five and sixty-five years of age an increase of 43 deaths, and at sixty-five years and over an increase of 68 deaths.

The death-rate for the first fourteen weeks of 1914 was 15.57 per 1000 of the population as against 15.77 for the corresponding period of 1913, a decrease of .20 of a point.

APPOINTMENT OF DR. WILBUR.—It was announced at Albany on April 6 that Dr. Cressy L. Wilbur, of Washington, D. C., chief statistician of the United States census bureau, has been appointed head of the new division of vital statistics in the New York state department of health, at a salary of $4000 a year.

MEDICAL JUDGES AND INSANE CRIMINALS.—A bill has recently been brought before the state senate at Albany, providing that in each county there shall be a medical judge who shall attend any trial at which medical evidence is taken concerning the sanity of a party to an action, and shall give medical advice to court and jury, his instructions to have the same weight as those of a trial judge. It is also proposed that the clause in the penal code enabling a verdict of "not guilty by reason of insanity" be changed to "guilty but insane." This would prevent the acquittal of dangerous criminal lunatics, and would also prevent insane criminals from securing writs of *habeas corpus*. It is reported, however, that the Governor will veto this bill on the ground that it would virtually abolish capital punishment. The measures are recommended by the State Bar Association.

ANTI-PNEUMOCOCCUS SERUM.—A press report on March 25 states that the Rockefeller Institute for Medical Research has announced the preparation by Dr. Rufus Cole of an anti-pneumococcus serum for the treatment of pneumonia. The serum is prepared like that of diphtheria, from the horse.

RECOMMENDATIONS FOR BELLEVUE HOSPITAL.—The hospital investigating committee of the Board of Estimate and Apportionment has made a report in which are described the deplorable conditions which have existed at the old "dead house" at Bellevue Hospital, N. Y., on account of the lack of room, and recommends the appropriation of $12,000 for the maintenance of a new one. It is also recommended that the state law concerning autopsies be amended so as to enable hospitals to make a much larger percentage of autopsies than is now possible. The reports goes on to say: "Bellevue Hospital has built and equipped the finest pathological building in the United States, and probably the best in existence. It is provided with every modern facility for performing autopsies and following up such autopsies by experimental work upon tissues; but, although the hospital has provided itself with this exceptionally well-designed and thoroughly equipped building, it is practically unable to use it, because of the inability to secure permission to perform autopsies. So long as it is impossible to perform a larger percentage of autopsies medical knowledge in the United States will lag behind that of Europe, and advancement will naturally be slow. . . The conclusions to be drawn from the large percentage of errors in clinical diagnoses revealed in the records of Bellevue are not that the findings of the attending physicians are carelessly made and recorded, but rather that too great reliance is placed upon inexperienced house physicians and internes, and also that the current knowledge necessary to make clinical diagnoses which shall approach accuracy is insufficient.

8. Austin discusses the pharmacological action of hexamethylenamine and describes chemical tests for free formaldehyde in the fluids of the body. He says it is the duty of every physician who gives the drug to make one of these tests. The antiseptic value of hexamethylenamine in the alkaline fluids of the body is nil, for the conversion of this substance into formaldehyde will not occur in an alkaline medium. The ordinary dose of 5 to 7½ grains three times a day is not sufficient to be of any antiseptic value, even in acid urine. Ten to forty grains every four hours are necessary to insure germicidal action of the formaldehyde in solution. [L. D. C.]

3. This author publishes a very thorough paper on formaldehyde. He finds that the drug has no field of usefulness in medicine other than for local use.

4. The authors found that five injections of neosalvarsan combined with intensive mercurial treatment have failed to show as good curative results, as shown by the serum reactions, as did one dose of salvarsan. In order to "cure" 70 or 80% of cases it would be necessary to use four or five times as much neosalvarsan as salvarsan.

6. Lindeman's article is of value and practical interest. The simplicity of his technic appeals. His analysis of results is valuable.

7. The authors transfused 500 c.c. of peripheral blood from a healthy male donor into a brother suffering from severe diabetes mellitus and obtained a marked rise in the output of sugar, ammonium and acetone bodies and glucose. They conclude that such transfusion is contraindicated in severe diabetes mellitus. [E. H. R.]

1. Stewart reports on a study of the blood flow in the hands and feet in arteriosclerosis, aortic aneurysm, Raynaud's disease, obliterative arteritis, gangrene, and angio-neurotic edema. He found that in cases with marked arteriosclerosis the blood flow in the hands was smaller and the contralateral vasomotor reflexes less pronounced than normal. In thoracic aneurysm the flow in the hands may be normal. When it is subnormal there is no evidence that the existence of the aneurysm as such has any influence in diminishing the flow; the diminution is due to coexisting pathologic conditions, *e.g.*, myocardial changes, valvular lesions. A great difference in the form of the pulse wave in the two radials associated with thoracic aneurysm does not necessarily indicate a difference in flow through the hands. In the cases of Raynaud's disease the hand flows were subnormal, even in the absence of an actual attack, and very much below the normal in the more advanced cases. An abnormally great contralateral reflex vasoconstriction to cold seems to characterize the earlier stages of this disease.

3. Folin, Denis and Seymour studied the non-protein nitrogenous constituents of the blood in arteriosclerotic nephritis and the effect upon them of variations in protein ingestion. Their results indicate that the direct determination of non-protein nitrogen and urea in the blood is a more reliable guide to the protein tolerance of patients than can be obtained from the phenol sulphonephthalein test or any other direct test of renal efficiency.

4. Wilbur and Addis made an exhaustive clinical and experimental study of urobilin, and their conclusions upon its clinical significance are valuable. The intestinal formation of urobilin from the decomposition of bile present within the bowel is the usual mode of origin, but there is evidence that a diseased liver may originate urobilin either directly as a product of its cells or indirectly from decomposition of bilirubin within the bile passages. Under these circumstances the accumulated urobilin in the liver is absorbed by the blood stream and excreted in the urine. There is a close association between increase of urobilin in the urine and disturbance of liver function. An increased quantity of urobilin in the stools indicates increased blood destruction. The interpretation of urobilin findings in the urine is somewhat problematical, while the determination of an increased intestinal excretion rests on a much firmer basis. Urobilinuria occurs almost constantly in the hypertrophic stage of hepatic cirrhosis. The degree of urobilinuria is a good index of the damage done to the liver parenchyma by chronic passive congestion, a marked degree of it being of ominous prognostic significance in cardiac decompensation. Urobilinuria is absent in obstructive jaundice, present in hematogenous jaundice. In obscure febrile conditions it is of diagnostic importance. The persistence of urobilinuria after malarial attacks in the absence of fever and of urobolin in the stools indicates cirrhosis, abscess or some other complication. In pernicious anemia total urobilin elimination is very large, in secondary anemia comparatively small. In pneumonia early and marked urobilinuria is a bad prognostic sign. Severe nephritis, even in the presence of increased production of urobilin, may prevent definite urobilinuria, so that large amounts of urobilin in the urine may be taken as indirect evidence of a certain degree of efficiency in the renal epithelium.

5. Newburgh and Lawrence studied the effect of heat on blood pressure in a series of experiments on cats and rabbits. They have found that degrees of hyperthermia not greater than those encountered in infections are sufficient to cause marked hypotension. The increased body temperature of infection is a potent factor in the production of the lowered blood-pressure which occurs in such conditions, and may be the entire cause of it. [L. D. C.]

JOURNAL OF EXPERIMENTAL MEDICINE.

1. Clark, Fraser and Amoss were unable to infect monkeys with specimens of human blood taken during the paralytic stage of poliomyelitis. In only one instance out of ten tests were they able to produce infection with a specimen of blood from experimental poliomyelitis in monkeys. In general their experiments showed that infection is accomplished far less readily through the circulation than by means of the more direct lymphatic and nervous channels of communication with the central nervous system.

8. Evans, Bowman and Winternitz carefully studied the histogenesis of an experimental miliary tubercle, developing inside the liver lobules in animals that have been vitally stained and inoculated with bovine tubercle bacilli. It is of considerable interest that the effects of the dye and of the tubercle bacilli are somewhat similar. They were able to show that the mononuclear cells which enter most actively into the reaction induced by the tubercle bacilli are endothelial and not hematogenous in origin. [R. I. L.]

5. FARRANT, R. *The Pathological Changes of the Thyroid in Disease.*
6. HUGHES, B. *Case of Acute Suppurative Appendicitis Complicated by Gangrene of the Ileum.*

1. Goodhart discusses glycosuria, in contradistinction from diabetes and its relation to retinal changes occurring in the course of arteriosclerosis and renal disorders—known as "gouty glycosuria." The latter part of his paper he devotes to albuminuria of adolescence its causation and diagnosis.

2. In his second lecture, Gilford continues his discussion of infantilism as associated with anomalies of sex organs, thyroid insufficiency, and abnormalities of the pituitary gland. He goes into the historical side of the question and gives much interesting information on the general subject.

3. Sherman presents conclusions from his detailed study of the morbid anatomy of tuberculosis in man as follows: Hypersensitiveness due to a primary infection is probably of great importance in relation to reinfection, not necessarily from a primary focus but from a new infection from without. The majority of cases of pulmonary tuberculosis are due to aerogenic infection, although retrograde infections do occur. There is no evidence in favor of a spread by direct continuity from the deep cervical glands to the lungs. In children manifest pulmonary tuberculosis is often a sequel of bronchial gland tuberculosis. In Scotland bovine infections in childhood are commoner than in most other parts of the world. There is much of interest and value in this article. [J. B. H.]

2. BRADBURN, T. S. *Oral Sepsis Simulating Henoch's Purpura.*
3. STEWART, P. *Further Note upon a Case of Hysterical Monoplegia Following Electric Shock.*
4. *SHUFFLEBOTHAM, F. *The Milroy Lectures on the Hygienic Aspect of the Coal Mining Industry in the United Kingdom. Lecture II.*

1. Osler interestingly describes certain manifestations of purpura, other than skin lesions, which occur in the course of the disease. These are of two types, mechanical, due to the presence of an exudate in the walls of the stomach, intestines, or elsewhere, and second, inflammatory, as nephritis, pleurisy, endocarditis, etc. He presents various interesting cases showing cerebral manifestations, ocular lesions, gastro-intestinal symptoms, angio-neurotic edema, epistaxis and renal complications, cardiac and respiratory lesions.

4. Shufflebotham, in his second lecture on the hygiene of coal mining, takes up the causes of explosions and their prevention by watering of coal dust, etc. He considers the various poisonous gases, such as black damp, fire damp, after-damp, etc., the treatment of cases of asphyxiation from such causes, and last he refers to rare causes of poisoning, such as sulphuretted hydrogen, smoke, nitrous fumes, et al.

1. *HOLMES, G. *The Diagnosis of Tabes Dorsalis.*
2. *CAMPBELL, H. *The Treatment of Syphilis of the Nervous System by Intrathecal Injections.*
3. *MCILROY, A. L. *Some Problems in the Treatment of Venereal Diseases.*
4. *ABRAHAM, J. J. *Arseno-therapy in Syphilis with More Particular Reference to "Gabyl."*
5. BAYLY, H. W. *The Diagnosis and Treatment of Chronic Gonorrhea and Its Local Complications.*
6. BARNES, A. E. *A Case of Otitic Meningitis and Cerebellar Abscess with Recovery.*
7. *SHUFFLEBOTHAM, F. *The Milroy Lectures on the Hygienic Aspect of the Coal-Mining Industry in the United Kingdom. Lecture III.*

1. This is a practical article on the diagnosis of tabes, but presents nothing new.

2. Campbell believes that the injection of salvarsanized serum into the spinal cord is the only effective way of treating certain forms of syphilis of the central nervous system. It should be begun as early as possible. It acts by destroying the spirochaetes within the central nervous system and the cerebrospinal fluid.

3. Among the preventive methods in handling the venereal problem, McIlroy recommends that all measures to prevent compulsory prostitution be encouraged; that the mentally deficient be segregated; that the public be educated as to the seriousness and size of the problem and that prompt notification of all abortions and premature births be made. In curative methods he urges that everything be done to keep patients under observation as long as possible and that this be only in the hands of the medical profession. He does not believe in special hospitals for such cases.

4. Abraham is of the opinion that mercury is regaining its old position as the main standby in the treatment of syphilis; that the real progress of arseno therapy is not in effecting a complete cure but in bringing about a rapid healing in the early, highly contagious stages of the disease.

7. In the third Milroy Lecture, Shufflebotham considers dust and its effects, particularly as regards tuberculosis and fibrosis. He discusses the symptoms and signs of the fibroid lung and then takes up the influence of temperature on the health of miners.

Obituary.

JOSEPH D. BRYANT, M.D.

DR. JOSEPH D. BRYANT of New York, professor of surgery in the University and Bellevue Hospital Medical College, died from diabetes in St. Vincent's Hospital on April 7. Dr. Bryant was born at East Troy, Wis., on March 12, 1845, and was graduated from Bellevue Hospital Medical College in 1868. He then served as interne at Bellevue. During almost his entire professional career he was connected in some capacity with the hospital, and for many years had been attending surgeon. In 1898 he was appointed professor of surgery in the Bellevue Medical School, and when the consolidation of this with the medical department of New York University was effected he was made professor of surgery in the new medical college. He had been visiting surgeon to St. Vincent's Hospital for twenty-seven years, and at the time of his death was also consulting surgeon to the Gouverneur, Woman's, and Manhattan State Hospitals, the Hospital for Ruptured and Crippled, and St. Joseph's Hospital, Yonkers. Dr. Bryant was the physician and confidential friend of Mr. Cleveland, both when he was governor and president, and by him was appointed state commissioner of health and surgeon-general of the state national guard. He was greatly honored by the profession, serving at various times as president of the New York State Medical Association, the Medical Society of the state of New York, the New York Academy of Medicine, and the American Medical Association. He was the author of an elaborate work on operative surgery, and collaborated with Dr. Albert H. Buck in the chief editorship of the "American System of Surgery."

Miscellany.

ANOTHER METHOD OF PROVIDING DENTAL NURSES.

IN the issues of the JOURNAL for Jan. 1 and 22 (Vol. clxx, pp. 24 and 139) we commented editorially on the proposed measure, now pending before the General Court, providing various changes in the methods of registration of dentists in Massachusetts. At a recent meeting of the Massachusetts Society for the Advancement of Mouth Hygiene, this measure was strongly disapproved. The society favors the accomplishment of the same end by adopting the following amendment to the present law regulating and governing the practise of dentistry in the state:

"Nor shall the law prevent a person, male or female, from cleaning the teeth of and teaching mouth hygiene to the children in public or private schools or institutions approved therefor by the board of health of the city or town in which such school or institution is located, which approval upon written application by the authorities of such school or institution said board of health in its discretion is hereby authorized to give, provided that such person is 20 years of age, of good moral character, has duly qualified

by passing a satisfactory examination in the subjects of mouth hygiene, sterilization, transmission of infectious and contagious diseases and the cleaning of teeth, and holds a certificate to that effect from the board of registration in dentistry, and upon the payment by each applicant of a fee of $5, which shall not be returned. Such board is hereby authorized to make such examination and issue such certificate."

The annual report of the Massachusetts State Board of Registration in Dentistry, recently filed, also opposes the establishment of dental nurses on the ground that in private offices they would be likely to practise other dental procedures than teeth-cleaning.

"Conviction for practicing dentistry by these certified 'dental nurses' would well nigh be impossible," says the report. "Obviously, the objection must be apparent. The passing of such a bill would be the opening of the door to an indiscriminate lot of unqualified adventurers to the general practise of dentistry and a virtual repeal of the present law. Therefore, the work of these qualified 'nurses' should be strictly limited to public and private hospitals, schools and charitable institutions.

Correspondence.

THE FRIEDMANN SERUM AND THE SOCIETY OF GERMAN SANATORIUM PHYSICIANS.

NEW YORK, April 7, 1914.

Mr. Editor: A sensational notice appeared at the beginning of last month in some of the leading New York American and German-American newspapers in which it was stated that on the occasion of the annual meeting of the Association of German Sanatorium Physicians on Febrbuary 28, one hundred and twenty of these physicians had carefully investigated the results of Friedmann's work. It was reported that 40,000 cases had been treated with Friedmann's serum and that the successes had been simply phenomenal. It was furthermore stated that Dr. Friedrich Franz Friedmann had been the guest of honor at a banquet given by the sanatorium physicians and that he had been effusively thanked by Privy-Councillor Professor Dr. Pannwitz for his work, in the name of the sanatorium physicians present. Finally, it was said in the newspaper report that Dr. Friedmann had made the statement to an American press representative that Professor Ehrlich had expressed the opinion that the Friedmann serum was absolutely harmless.

In a communication received by the undersigned, bearing the signatures of the President, Dr. O. Pischinger, the Vice-President, Dr. J. Ritter, and the Secretary, Dr. Schellenberg, of the Association of Sanatorium Physicians of Germany, Austria and Switzerland, he was requested to enlighten the American medical profession concerning the incident connected with their visit to the Friedmann Institute in Berlin, and to give the facts the widest possible publicity at least among medical men.

First of all, the officers of the association expressed their astonishment that the visit of the sanatorium physicians to the Friedmann Institute should have been used as a means of advertising Friedmann and his remedy abroad. Because of the report of cures which constantly crept into the German medical and lay press and the demands for the remedy from many sanatorium patients, it was natural that the sanatorium physicians while visiting Berlin should wish to see for themselves what was going on in the Friedmann Institute. Thus they asked Friedmann to show them his cases and give them a talk on the indication for his remedy. About 60 of the 125 members of the association visited the Friedmann Institute on the 26th and 27th of February, 1914. They distinctly stated that their visit was in no way to be considered a pilgrimage to pay homage to Friedmann for his discovery but rather an investigation to find out just how much truth there was in his claims. Many had already tried the remedy and had been disappointed, others were prejudiced, and it is for this reason that they wanted to examine critically into Friedmann's claims. It is absolutely untrue that a banquet was given to Dr. Friedmann. After the conclusion of the visit there was a confidential conference, without Dr. Friedmann, at which the members concluded to discuss the theme again next fall and in the meantime collect as much material as possible.

That the undersigned may not be accused of prejudice or misinterpretation, I wish to quote in German the most essential statements which were made as the result of the visit of the association to the Friedmann Institute:

"Wir waren uns darüber einig, dass die uns von Friedmann gezeigten Fälle klinisch recht schlecht beobachtet waren und im Allgemeinen keineswegs als 'Erfolge' angesehen werden konnten. Wir haben uns gewundert, dass uns keine ordnungsmässig geführte Kurve gezeigt wurde. Die Röntgenplatten, die man uns zum Beweis zeigte, bewiesen tatsächlich garnichts. Wir geben zu, dass einzelne Fälle allerdings einen gewissen Eindruck auf uns gemacht haben, *wobei wir uns aber auch darüber klar waren, dass solche Fälle auch ohne jede Behandlung und bei jeder Behandlung vorkommen können*, und dass die Zahl dieser Fälle verhältnissmässig *viel* zu klein war, um ein günstiges Urteil über das Mittel abgeben zu können."

(We were of the unanimous opinion that the cases shown by Friedmann had been clinically very badly observed, and as a whole could not be considered as successes or cures. We were astonished that no carefully recorded temperature and weight curves were shown. The x-ray plates which were shown to us as evidence of cures did not actually prove anything whatsoever. We will admit that some cases indeed made an impression upon us, but here we must also remember that such cases occur without any treatment or with any kind of treatment, and that the number of them were altogether too few to permit a favorable judgment of the value of the remedy.)

I have since received a letter from Geheimrat Professor Dr. Pannwitz in which he substantiates what has been said in the official communication from Drs. Pischinger, Ritter and Schellenberg. He particularly expresses his indignation at the use of his name in connection with a banquet which never took place. He declared the whole thing to be a newspaper invention.

Prof. Dr. L. Brauer, Director of the Eppendorf Krankenhaus of Hamburg, who had also heard the American version of the sanatorium physicians' visit to the Friedmann Institute in Berlin, wrote me a letter full of indignation and said at the same time that "he had tried Friedmann's remedy at the Eppendorfer Krankenhaus and the results had been unfavorable." He has reported these unfavorable results recently at the Balneological Congress and the Hamburger Aerzte Verein, and intends to publish more on the subject at an early date. He has since sent me the advance sheets of his forthcoming communication regarding Friedmann wherein he says: "The pulmonary cases tested in the Eppendorfer and Salemburg hospitals with Friedmann's method did not improve, but some of them without a shadow of doubt were rendered worse by the treatment. Five cases of bone and joint tuberculosis in children treated with the Friedmann serum by Dr. Trepler in the Salemburg institution were not influenced at all by the treatment and in

one case, although the movement of the afflicted joint increased, the general condition of the lesions was rendered worse."

In paying a gratifying tribute to the earnest and unbiased work done with Friedmann's serum by American investigators, which likewise gave unfavorable results, Professor Brauer advised me, in the interest of the German medical profession, and especially in the interest of the unfortunate patients who naturally are inclined to accept such advertised endorsement as genuine, that it would be most desirable for the present status of the Friedmann remedy in Germany to be made clear to the American medical profession and the laity.

I am sure our German colleagues in general and particularly the German sanatorium physicians, Professors Pannwitz and Brauer, will be greatly indebted to you, Mr. Editor, if you will give the foregoing a space in your esteemed journal and thus make clear the real status of Friedmann's remedy in Germany.

Respectfully yours,

S. A. KNOPF, M.D.

CHANGES IN THE MEDICAL CORPS, U. S. NAVY, FOR THE WEEK ENDING APRIL 4, 1914.

March 27, Surgeon G. F. Freeman, from *North Carolina* to the *Nebraska*.

P. A. Surgeon E. H. Old, detached, *Nebraska* to wait orders.

March 28, Medical Director G. T. Smith, detached, Navy Yard, Washington, D. C., to wait orders.

Surgeon C. E. Riggs, detached, *Louisiana* to wait orders.

Surgeon F. C. Cook, detached, Naval Hospital, Puget Sound, Washington, to *Louisiana*.

April 1, Asst. Surgeon J. T. Boone, commissioned asst. surgeon, M.R.C., March 17, 1914.

April 2, P. A. Surgeon D. C. Walton, detached, Naval Hospital, Brooklyn, N. Y., and ordered to Naval Academy, Annapolis, Md.

Asst. Surgeon C. I. Wood, M.R.C., to New York Hospital.

EXAMINATION OF CANDIDATES FOR ASSISTANT SURGEON.

TREASURY DEPARTMENT.

UNITED STATES PUBLIC HEALTH SERVICE.

Boards of commissioned medical officers will be convened to meet at the Bureau of Public Health Service, 3 B Street, SE., Washington, D. C., and at the Marine Hospitals of Boston, Mass., Stapleton, N. Y., Chicago, Ill.; St. Louis, Mo.; New Orleans, La.; and San Francisco, Cal., on Monday, April 27, 1914 at 10 o'clock a. m., for the purpose of examining candidates for admission to the grade of assistant surgeon in the Public Health Service, when applications for examination at these stations are received in the Bureau.

Candidates must be between 23 and 32 years of age, graduates of a reputable medical college, and must furnish testimonials from two responsible persons as to their professional and moral character. Service in hospitals for the insane or experience in the detection of mental diseases will be considered and credit given in the examination. Candidates must have had one year's hospital experience or two years' professional work.

For investigation to appear before the board of examiners, address "Surgeon General Public Health Service, Washington, D. C."

APPOINTMENTS.

DR. L. D. BRISTOL, of Syracuse Medical School, has recently been appointed director of the public health laboratory of the University of North Dakota.

RECENT DEATHS.

DR. JOSEPH B. BRYANT, of New York, died in that city on April 7, at the age of 69 years.

DR. G. P. DAVIS, who died on April 1, at Hartford, Conn., was born in 1845. He graduated from Yale in 1865, and in 1869 received the degree of M.D. from the New York College of Physicians and Surgeons. He was a former president of the Connecticut State Medical Society.

DR. PHILIP MANSFIELD FITZSIMMONS who died on April 4 at Cambridge, Mass., was born in Ireland in 1863. He migrated to the United States in 1889, and in 1892 received the degree of M.D. from the University of Vermont. He settled in the practise of his profession at Cambridge, where he served as medical inspector of schools. He was a member of the American Medical Association, a Fellow of The Massachusetts Medical Society, and a member of the Cambridge Medical Improvement Society. He is survived by one daughter and one son.

DR. F. J. S. GORGAS, formerly dean of the dental department of the University of Maryland, died at Baltimore on April 8, at the age of 80 years.

DR. ALLAN FOSTER BARNES, of Cambridge, a Fellow of The Massachusetts Medical Society, died at the Massachusetts General Hospital, Boston, April 12, 1914, aged 38 years.

THE TREATMENT OF CASES OF MENTAL DISORDER IN GENERAL HOSPITALS.*

By Philip Coombs Knapp, A.M., M.D., Boston,

Physician for Diseases of the Nervous System, Boston City Hospital.

In the report of the Boston City Hospital for the year ending January 31, 1913, the trustees, speaking of the establishment of the house service for nervous diseases, made the following statement:—

> "With the passage of time the advantages of this plan become more evident. Perhaps the most marked gain for the hospital is in the opportunity this service gives for the observation of patients with psychopathies, or confusional or hallucinatory states. In this way there is given the opportunity to distinguish the various forms of cases, particularly to separate the cases due to some toxaemia or other temporary causes from the more chronic cases, thus preventing the need of committing many of these patients to institutions for the insane, and thus saving them from the stigma of having been insane, however unreasonable this stigma may seen to physicians, and also avoiding considerable expense for the community for the transfer to other institutions of these transitory cases."

In the many discussions that have been held as to the disposition to be made of the so-called "acute and borderland cases of mental disease," I have at various times contended that such cases could very well be received and temporarily cared for in our general hospitals,—a contention which the hospital authorities have always strenuously opposed. It was therefore with considerable gratification as well as surprise that I read the words just quoted, for they showed that the experience of the last four years in the treatment of such cases in the neurological service has demonstrated not only that the admission of such cases is possible, but even advantageous.

The mentally disturbed patient is, of course, not looked upon with favour in a general hospital. He may be noisy, violent or dangerous; patients and nurses fear him; he may have to be fed or be filthy in his habits; his language and conduct may be offensive; he may even kick off the bed-clothes or wander about in his night shirt. Consequently a matron, who does not want the bed-clothes thrown off when the thermometer reaches 104°, or who, like the matron described by Dr. Mary Neff*, "wants the patients to sit all in a row," because they "look neater that way," looks at him askance. His departure, whether to the insane hospital or the morgue, is hailed with relief. Nevertheless every hospital of any size must inevitably have to deal with disturbed or violent cases, if it receives accident cases, surgical cases, acute infectious diseases, apoplexies, renal diseases, or, I might almost say, any patient at all. If the hospital has a special ward, like the psychiatric ward at Bellevue, the problem is easier, but with open wards the difficulties are obvious and have often been regarded as insuperable.

It therefore seems desirable, especially in the light of the recent comments of the trustees of the hospital, to review my own personal experience in the last four years in dealing with patients who have manifested some mental disturbance during their stay in the hospital. I will speak only of the cases admitted to my own service during one half of each year, although it is safe to assume that conditions do not differ materially during Dr. Thomas's service in the other half of the year. It is fitting here to recognize Dr. Thomas's complete cooperation in the work of the service in caring for these patients and the absolute support which Dr. McCollom has given us, in spite of certain anxious misgivings, in our efforts to carry out our own ideas in the face of considerable opposition and interference on the part of others.

A few words of explanation may be desirable in regard to the Neurological service. After a struggle of twenty-three years, following the abolition of the service in 1886, it was re-established in July, 1909. Twenty beds were allotted to the service,—an inadequate number, for the service has contained at times thirty or forty patients. There is no special ward, but patients are distributed in several wards. Excited patients are put in an open ward of eight beds, or in double rooms opening on a corridor leading directly from this ward. The doors are not locked and access is free. About four hundred patients are admitted annually to the wards, chiefly adults. In addition the visiting physicians have charge of the out-patient department, which receives seven or eight hundred new cases a year. Cases are often referred from the out-patient department to the wards, but the great majority of cases admitted to the hospital come from outside and are never seen in the out-patient department. No special effort has been made to collect mental cases and recommend them for admission; they have come in simply in the course of the ordinary hospital routine. After some months the trustees passed

* Read at a meeting of the Boston Society of Psychiatry and Neurology, December 18, 1913, and at a meeting of the New York Psychiatrical Society, January 7, 1914.

* Journal of the American Medical Association, vol. lxi, p. 660, August 23, 1913.

a vote that all cases in the hospital in which the question of commitment was raised should be referred to the neurological department which should provide for such commitment if advisable. Such cases are usually, although not always, transferred to the Neurological service.

In the last four years there have been admitted to the service during the months when I was on duty 785 patients. Of these 49 were not neurological cases. The remainder may be classified as follows:—

Diseases of peripheral nerves	62
Diseases of spinal cord	78
Diseases of brain	279
Neuroses and psychoneuroses	157
Mental diseases	74
Alcoholism	93
Cases classed under two headings	7

This classification is the conventional one, classifying hysteria, epilepsy, psychasthenia, etc., among the neuroses, and including paresis among the mental diseases and cerebral oedema (alcoholic "wet brain") under alcoholism. The following table will show the diagnoses most frequently made.

Apoplexies (hemorrhage, embolism, thrombosis)	207
Alcoholism	93
Hysteria	52
Neuritis	40
Epilepsy	36
Tabes	35
Chorea	23
Cerebral syphilis	21
Dementia precox	20
Cerebral tumor	18
General paresis	14
Spinal tumor	11
Spinal syphilis	10

Under alcoholism I have included beginning delirium tremens, cases that never developed a true delirium, but came near it, alcoholic confusion, hallucinosis, paranoid states, pseudo-paresis and "wet brains." In addition most of the cases of neuritis were of alcoholic origin and many of them showed the Korsakow syndrome. The 74 cases of actual mental disease were of all types, senile dementia, paresis. dementia praecox, maniacal-depressive insanity, infectious psychoses, confusional states, etc.

This classification, however, is not very illuminating. Under the hospital rules mental and alcoholic cases, which form about twenty per cent. of my cases, are not supposed to be admitted. We must also remember that many cerebral cases, not classed as mental,—apoplexy, tumor, syphilis,—may show pronounced mental symptoms, that many cases of neuritis have Korsakow's syndrome, and that hysteria, chorea, epilepsy and psychasthenia can cause considerable disturbance, so that these "mental" cases are only a part, perhaps a minority, of the cases which show mental disturbance. If the cases admitted to Dr. Thomas's service are like those admitted to mine, which seems to be the case, it is not an exaggeration to say that the service receives about one hundred patients each year who show considerable mental disturbance. I may add that I have myself committed 69 patients from the hospital in the last four years, and I think that at present about forty such cases are committed each year.

The crucial point in regard to the admission of mental cases to the wards of a general hospital is, of course, neither the number of cases nor the diagnosis, but the conduct of the individual patient. A general paralytic may be able to go about and attend to business without harm to anything or anybody except the business, or he may be the most dangerous patient in an asylum. That many of our patients have been actually insane the number of commitments shows, but many have been fairly quiet and easily controlled, just like the majority of patients in an insane hospital. I have, however, dealt with nearly every variety of patient in these last four years as far as conduct goes,—simple confusion, cases requiring forced feeding, agitated and suicidal melancholias, aggressive paranoiacs and the most violent epileptic mania. Violent mania is of course rare, whether in a general hospital or an insane asylum, yet to the minds of many of the laity, and apparently some physicians, "insanity" seems to connote violent mania, if indeed it be not identical with it. In some of the discussions on the treatment of incipient and border-land cases of mental disease, I have often wondered just what the cases were, for they were depicted as so much more violent and intractable than the incipient and border-land cases I had met, that it almost seemed as if, in comparison with them, the first Mrs. Rochester—still the type of the insane person—were a Quaker damsel.

I do not mean to imply that, previous to the reestablishment of the neurological service, there were not mental cases in the hospital. On going over the records of the old service for nervous diseases thirty years ago, I have been surprised to note the very considerable number om mental cases admitted, and I can recall many cases each year since that have come under my observation as a consultant. Many alcoholic and some mental cases may still be found in the general services, so that there have been more cases in the hospital during the last four years than my statistics would indicate. Every general hospital actually receives a considerable number of such cases, and, although the hospitals object and profess not to receive them, they will continue to have them in their wards so long as they receive patients at all.

In most hospitals, however the mentally disturbed patient, like other unacknowledged children, is not very well treated. Even if he

be not actually violent he may get out of bed or disarrange the bed-clothes, and the one idea is to keep him quiet. The result is restraint, and since drug restraint usually requires the connivance of the physician, mechanical restraint, which can be applied without a prescription, is preferred. This is often irritating and sometimes brutal. With a sheet across the body, each hand tied down to the side of the bed and each foot tied to the bottom, it is a common thing for the patient, if he be restless, to rub several square inches of skin off his wrist and ankles. The exasperating effect of such restraint is obvious, and since he can get relief in no other way, he takes it out in cursing—and small blame to him. In hospitals for the insane a list is kept of all patients put under restraint, noting the kind of restraint and the length of time it is applied. Such a list is regularly submitted to the trustees on their visits, and the trustees usually visit such patients and investigate their condition personally. What general hospital does the same?

I am not disposed to make a fetish out of "no restraint." I have seen patients in insane hospitals where I believed at times restraint was desirable. In general hospitals restraint may be even more necessary, especially in surgical cases, but it is applied much oftener than is necessary. There is much truth in the statement that violent mania is often an artefact, due to psychical sepsis, and it is a fact that much of the restraint used in general hospitals is due to an inefficient and insufficient nursing force.

It naturally follows that an effort has been made to cut down restraint, in which Dr. Thomas thoroughly cooperated. House officers and nurses were told that mechanical restraint as ordinarily applied was damnable, and some of the former apparently came to believe it. Both house officers and nurses speedily became convinced that, if they employed restraint except as a last resort in urgent cases, they would be very thoroughly damned, and no restraint has been permitted except on the express orders of the house physician. In the enforcement of such rules and in the prevention of interference by matrons and executive assistants, we have been much helped by Dr. McCollom, who has always been ready to supply special nurses when necessary. The result has been that in the neurological service little restraint has been used, usually in the form of a sheet fastened across the bed, or, very rarely, of a camisole. The brutal "spatch-cock" method of tying, already described, has proved needless. Restless patients have often done well when side pieces were put on the beds—an innovation in the hospital which we owe to Dr. McCollom, and which would undoubtedly shock a matron who thinks things "look neater" if everything is uniform. The result has sometimes been shown in the remark of a house officer, "It's interesting to see how that patient quieted down after you took off the restraint he had on in the other service."

In endeavoring to do away with mechanical restraint, I do not think I have fallen into the excessive use of drug restraint. I have used the milder sedatives, bromide or veronal, in moderate doses in a good many cases, especially in alcoholic cases, but I have very rarely prescribed more powerful drugs, hyoscine, morphine or even chloral. An occasional wet pack, forced feeding, absolute avoidance of alcohol in the alcoholic cases, a few moderate doses of bromide and more or less persuasion have usually sufficed.

The question naturally arises, "What has been the result of all this? How can you get on in a general hospital and open wards with these excited, noisy patients if you do not restrain them?" In the first place most of these patients are not excited and noisy unless they are restrained. If the physician takes alarm at the first symptoms of aberration, restlessness or disarrangement of the bed clothes and applies restraint, the patient becomes irritated in consequence and is ready to make trouble. Even when the patient is excited and noisy we have managed to get on with very little restraint, and apparently we have done better without it. In four years there has been no suicide, no patient has escaped from the hospital, and only very rarely from the ward, and no patient has seriously injured himself or others. I speak solely of my own service, but I think the same holds true of Dr. Thomas's service. This is what any man with insane hospital experience ought to expect, but some have seemed disposed to question whether, without the regime of an insane hospital with locked doors and violent wards, no restraint was feasible in an open hospital ward. Cases will undoubtedly occur which will give rise to trouble—suicides, escapes, assaults,—but they occur even in hospitals for the insane, and they are not common. Cases of incipient mental disease, "border-land" cases requiring a period of observation to determine their mental state, even the emergency cases picked up by the police, can perfectly well be treated in the wards of a general hospital, as our experience in the last four years has shown. They make more trouble for the nurses and give them more work; they are a source of anxiety to the administration and the staff, but they can be dealt with without much harm, provided the physician knows how to deal with them.

Another question, which is often regarded as a bugaboo, is the legal status of these patients. It is urged that we have no legal right to receive such cases or to hold them against their will, or, if the patient be violent, to put him under restraint. This is perfectly true, and,

of course, a very serious difficulty to which we usually pay no attention. Once in a great while a patient has stood upon his legal rights and demanded immediate discharge, but a few excuses and delays have given time for the necessary steps for commitment, when it has been necessary.

Four years' experience has convinced me that, even without a special psychiatric pavilion or psychiatric wards insane patients can be received and temporarily cared for in the open wards of a general hospital with comparatively little restraint and that such a procedure is attended with somewhat more trouble, but no great risks. The question arises, however, what is the good of it all? The statement of the trustees gives a partial answer which merits a little more consideration.

In the first place, if mental cases be received in a general hospital, it is an easy way of dealing with cases of acute onset or the cases which fall into the hands of the police. A case of dementia praecox, suddenly attacked with mutism and found wandering about the town acting strangely, can be brought to the hospital without delay, without legal formalities and without waiting to hunt up his friends, and can receive immediate treatment, just as if he were attacked by apoplexy or were the victim of injury. This is often of advantage and it may prevent neglect or ill treatment, such as the insane used to receive in police stations. With a psychiatric hospital within easy reach, if admission be not made too difficult, it may, of course, serve the same end.

Still more important are the cases which do not fall in the hands of the police, but who either come of their own accord or are brought by their friends. In such cases the general hospital can be of great service to the community in three different ways. A patient may present obscure symptoms which make the mental state a fit object of inquiry. He can be subjected to observation until a definite diagnosis and suitable provision for his future can be made, without any disturbing legal procedure and without alarming the patient or his friends with immediate processes of commitment. A patient in the early stages of some mental disorder can be thus cared for until it is easy to determine what is best to be done. The family is often very loath to admit that there is actual insanity and shrink from the formalities of commitment even though the nature of the disease and its probable outcome are fully explained. They grasp at every straw to avoid commitment to an insane hospital and suggest home care, a sanitarium for nervous diseases and the like. If the patient be taken to a general hospital they have a chance to watch his condition for themselves and to realize his unfitness for anything but asylum care. The idea of his insanity gradually grows in their minds and they become more reconciled to accepting the inevitable than they would be if the experiment had not been tried. Time is afforded for family councils, for personal investigation of desirable hospitals and for a fuller realization of the patient's actual mental state. The general hospital thus exerts a beneficial and desirable influence by lightening the burden of a family in its time of distress.

Finally, cases of short duration can be treated in the general hospital until they are able to return home and can combine treatment as out-patients, on the "after care" principle, until recovery is complete, thus avoiding an official recognition of the "stigma of having been insane."

This stigma is of great influence upon the minds of the general public and it is by no means as unreasonable as we try to assume. It is unreasonable to regard insanity as a disgrace, but that belief is dying out, but it is not unreasonable to recognize the fact that insanity is to a considerable extent a stigma both economically and socially. The employer of labor, in the broadest sense of the term, may very properly question the efficiency of the employee who has been officially judged to be of unsound mind. Even if he has been allowed to go at large and has been pronounced recovered, has he the quickness of perception, the accuracy of memory, the intelligence, the judgment, the decision that are requisite? Is he as good as he was before or as good as the rival candidate who has never been adjudged insane? The answer to both these questions may be yes, but the employer is justified in asking them, and the mere fact that they can be asked excites a certain prejudice against the victim. It is his misfortune and not his disgrace, the question may be raised without any justification, but the previous insanity remains as a handicap, and the employer is justified in doubting his efficiency as he would be in doubting the efficiency as a look-out man of the applicant who wore ten dioptre glasses.

Furthermore, until our modern craze for eugenics has passed to that land of oblivion where Annie Rooney watches the march of the Mulligan Guards, some will doubt, perhaps wisely, perhaps without reason, even if the state is not sufficiently up-to-date to have a eugenic marriage law, whether M. or N., if once adjudged insane, is a fit person to be joined in holy matrimony.

If, therefore, a person suffering from some acute mental disease, which does not impair his mentality afterwards or influence his future offspring, can be treated without an official, legal recognition of his trouble, it may be of great advantage, a positive benefit to the patient and the community.

That such cases can be treated and get well in the wards of a general hospital, even if the conditions for their treatment be not ideal, has

been shown many times in the last four years. I will not go into details but indicate in a few instances what has been done.

A young musician, neurotic and with a bad family history, entered the hospital with a rather severe pneumonia attended with delirium. After the pneumonia had wholly cleared up he developed hallucinations, which seemed to him real, mental confusion and some delusions. He was transferred to the neurological service, where, after a time, the hallucinations began to lose their reality and the delusions subsided. He was encouraged to disregard his hallucinations and finally improved so much that he was able to go into the country with some friends. It seemed at first as if the trouble were likely to develop into dementia precox, but he eventually made a complete recovery.

A Russian Jew, speaking little English, came to Boston, where he met with some business disappointment. He was picked up by the police and brought to the hospital weak and cataleptic. Later he became confused and had hallucinations. He also seemed at first a typical dementia precox, but later, after the arrival of his wife and the straightening out of his financial troubles, he made a complete recovery.

An alcoholic patient was admitted to one of the medical services where he speedily developed delusions of persecution with hallucinations of sight, smell and hearing. Under the sway of these delusions he made a dramatic escape one night over the wall in his nightgown and was brought back by the police from Washington Street, where he was trying to board a car. He was transferred to the neurological service for commitment and gave a very dramatic account of his escape, detailing all the facts most accurately. After a few days of careful attendance and re-assurance his delusions disappeared and he recovered completely.

A police officer, markedly alcoholic, but who denied syphilis, was admitted to the laryngological service with edema of the glottis, and tracheotomy was performed. After that he became much excited, tried to escape and was noisy and troublesome. He showed marked euphoria, considerable exaltation, lack of comprehension, slurring speech and the inconsequential manner of a paretic. There was failure of memory, the handwriting was suggestive and the pupils sluggish. He had, however, considerable insight, and, when I saw him in consultation, knew who I was and that I had been called in to determine his mental state, and commit him to an insane hospital. The Wassermann test in the blood and cerebrospinal fluid was negative, the globulin reaction was negative and there was no increased leucocytosis. He began to show less excitement so that I resisted the pressure to commit him, and a few weeks later was able to send him to the country, where he made a complete recovery.

It is sometimes said that a general hospital is not adapted for the treatment of the insane because it has not the facilities of an insane hospital. It is not adapted for permanent treatment. It lacks the opportunities for work, entertainment, exercise, out-of-door life, and recreation which are such important factors in our modern hospitals for the insane. It has, however, certain advantages which are not to be wholly ignored. A few years ago a good deal was said about "bed treatment" in the early stages of the acute psychoses. That, of course, is what a patient is likely to get in the wards of the hospital. Furthermore, unless he be very demented or confused, he enters into an atmosphere of physical sickness which is inevitably impressed on his mind. He is in a ward with others who are manifestly sick persons, therefore there may be something the matter with himself, his hallucinations and delusions may be the product of physical disease. The suggestion of the hospital ward may help to establish an insight into his own condition. This, of course, may be a disadvantage in somatopsychoses of a hypochondrical nature, but in other cases it may do good. In some alcoholic cases of a paranoid type, where the patient insisted upon getting up and leaving the hospital, I have found that the suggestion that the patient was in the hospital with other sick people because he was sick himself, and that he ought to stay a little longer until he was better, actually worked, and the patient stayed until he recovered.

If, therefore, the Trustees can express themselves as they have in their last report, it is no emotional conversion but a simple recognition of what four years' experience has shown, that it is feasible for a general hospital, even without a special ward, a hydrotherapeutic plant and other aid, to receive and treat both doubtful and pronounced cases of mental disorder, with little restraint and without great risk of serious results; that it is also feasible to treat some cases of short duration until they recover; and that the reception and treatment of such cases is a benefit to the patient and his friends, by giving an opportunity for study of his condition, for deciding upon the proper disposition of the case, and, perhaps, by preventing the stigma which actual commitment may inflict.

I would go a step further and say that it is the duty of every large general hospital to take such cases. The mental patient has a claim upon the benefits of a public hospital just as well as the surgical, the gastric or the renal patient. To be sure the reception of such cases means some extra trouble, a few more nurses and more anxiety for the staff and the administration. The adoption of aseptic methods in the surgical wards meant much more trouble and vastly greater expense. There are certain risks involved, but our experience, though limited, has shown that they are not very great. Every good hospital for the insane has its escapes, its suicides, its act of violence. The general hospital may expect them as well; they are a part of the game, but the benefits to the community outweigh them.

One word in conclusion. It is not practical to receive and care for such patients in a general hospital unless there be a special service under the charge of a visiting neurologist familiar with mental diseases and their treatment. The average American internist is too ignorant of mental and nervous diseases to deal properly with such cases. Something more is requisite than restraint while in the hospital and commitment at the earliest opportunity. The visiting physician must be familiar with mental diseases, he must be able to make a sound prognosis as well as diagnosis, must know how the patient is likely to behave and be ready to assume risks and to take proper precautions. He must have the control of his patients and their treatment without interference from administrative officers, and must be alone responsible for the treatment, the stay in the hospital, restraint and commitment. Only under such conditions can the reception and treatment of cases of mental disorder in general hospitals be of full benefit to the patient and the community.

[Since reading this paper I have learned from Dr. H. M. Adler that, at the Psychopathic Hospital, they had recently compared the death rate from alcoholism at several different hospitals, and that, since the establishment of the neurological service at the City Hospital the death-rate from alcoholism at that institution, in spite of defective facilities for treatment, has been reduced one-half.]

MEDICAL INSPECTION OF IMMIGRANTS AT THE PORT OF BOSTON.*

BY A. J. NUTE, B.S., M.D., BOSTON,

P. A. Surgeon, United States Public Health Service, U. S. Immigration Station, Boston, Mass.

While the above heading is given as the subject this evening it applies in general to all ports of the United States. The story of immigration is as old as the history of the United States; in fact with certain qualifications it is the history of this country. While laws in the early days provided for the restriction of inanimate goods, more or less unwritten and written law restricted the human being from certain localities, which finally grew into organized law for the protection of the community. For example the Quaker was not welcome in the land of the Puritan and Virginia gradually closed the door to redemptioners. Our institutions have been founded by, supported by, and in turn supported aliens and their descendants. The first rule of national life is self preservation and as immigration still has an important rôle in America national life it must be carefully scrutinized to admit the desirable.

The medical aspect of immigration was brought to public notice about the year 1824 when New York City attempted to levy a head tax on all foreign passengers arriving in that city; later in 1847 a similar act was passed by the state. This money was intended for the support of an immigrant hospital. It was declared unconstitutional in both cases by the courts on the ground that the power to regulate commerce was vested in Congress and not in any state.

This was probably the first restrictive policy that was actively started but of course the whole earlier history of the country showed that economic pressure tended to restrict newcomers to those nearest the race, language and ideals of the region. For many years each state dealt with the problem of restricting the entry of diseased aliens as best they could. Of course this was very difficult owing to the ease of passing from one state to another.

When the Federal Government took supervision of the matter in 1882 a general rule was adopted to reject those who suffered from physical defects liable to make them public charges, note being made of insane, idiots and persons unable to take care of themselves. In 1891 this law was further extended to include those suffering from loathsome or dangerous contagious diseases. In 1903 the most radical step was taken when the Government placed a fine of $100 on the steamship company, in addition to exclusion, for each case of a loathsome or dangerous contagious disease that could have been detected by competent medical inspection at the time of embarkation. In 1907 the law was extended to exclude epileptics, feeble-minded and persons who have been insane within five years, or have had two or more attacks of insanity at any time previously, tuberculosis (meaning tuberculosis of the lungs, intestinal tract or the genito urinary system) or those suffering from such mental or physical defect which may affect the ability of the alien to earn a living. At the same time idiots, imbeciles and the tubercular were placed in the $100. fine class. In 1891 Congress turned the work of medical inspection over to the Marine Hospital Service (now the Public Health Service.) This Service has published definite rules for the medical examination of aliens which if followed insure a uniform system of inspection and records at all ports of entry.

Whether an immigrant belongs to the excluded class or not is a function of the immigration officials. This is often confusing to many for it must be understood that the Immigration Service is a Bureau of the Department of Labor and the Public Health Service is a Bureau of the Treasury Department. Hence the two Bureaus work together; the certificate of the medical officer constituting the legal evidence

* Address given before the Norfolk District Medical Society, Boston, Mass., Jan. 27, 1914.

upon which the immigration officials base their action, in mandatory cases and in other cases consider the certificate from the standpoint of affecting ability to earn a living or likely to become a public charge. Seldom does the alien suffer from too harsh a medical judgment. All things taken into consideration he gets the best end of the doubt for the rules require the certificate to be based on conclusive evidence. For example a case of pulmonary tuberculosis cannot be so certified unless a microscopical slide showing the bacilli can be demonstrated.

Briefly the law divides all defectives into three classes and makes no distinction between cabin and steerage passengers. United States citizens of course are exempt from examination but may be called upon by the immigration officials for satisfactory evidence of citizenship.

CLASS A. Mandatory exclusion because of definite specified diseases such as idiocy, imbecility, feeble-mindedness, insanity, epilepsy, tuberculosis, loathsome or dangerous contagious diseases.

CLASS B. Aliens not under Class A., but present some defect or disease affecting ability to earn a living, as hernia, heart disease, defective nutrition, varicosities, presenility, certain diseases of the nervous system, chronic joint diseases, marked defective vision and tuberculosis of the skin, glands and joints.

CLASS C. Aliens presenting defects or diseases of less seriousness but must be certified for the information of the immigration officers that they may pass intelligently on the case.

In order to prevent any alien slipping by without examination by doctor every passenger carries an identification card. In the cabin this card is punched as each alien passes the medical officer so that the inspector can tell at a glance whether or not he has been seen. As the immigration inspectors are on the alert they usually return to the doctor any alien who presents any unusual physical or mental appearance even if his card is punched. To prevent delay a slight abnormality such as a scar of the face from a burn is noted by the doctor and a slip given the alien noting the condition and stamped "Special Medical Passed." The steerage usually being examined on shore are checked by attendants to prevent any oversight. At Ellis Island the steerage passengers' inspection cards are stamped in ink by an attendant.

In the law contagious means communicable and loathsome contagious mean those whose presence excites abhorrence and are essentially chronic such as favus, ringworm of the scalp, leprosy venereal diseases. Dangerous contagious diseases may be illustrated by trachoma, hookworm and amoebic dysentery.

The method of conducting examination must vary somewhat with local conditions and to accomplish this without undue annoyance to travelers, without delaying traffic requires care and tact on the part of the medical officer. Before inspection two sources of information are at hand; the manifest sheet and the ship surgeon's report. How reliable this information is depends on the type of men filling the forms. When one considers that nearly all immigration is carried in foreign ships manned by foreign officers it requires experience in dealing with them to estimate the value of their reports. As far as possible all inspections should be made in daylight for under artificial light certain diseases involving different hue or alteration in the skin cannot be noted accurately.

The medical examination is divided into two parts, primary and secondary. In the primary the efforts of the examiner is directed toward segregating from among those presented those suspected of having disease, defect or abnormality of any kind in order to enable the healthy to proceed without unnecessary delay. Secondary; to make a systematic inquiry as to the signs and symptoms in those turned aside in order to determine a diagnosis and proper certification. The alien may be detained for any reasonable period of observation required to complete the diagnosis and if necessary hospital treatment provided.

Primary inspection is conducted on an even level surface, so that the passenger may not be tempted to look where he is stepping. Care is taken against crowding, to maintain a line evenly spaced and to have as little baggage carried as possible. The examiner stands in a position to secure as even illumination as possible. Direct sunshine in the face or reflected from the water must be avoided. To also facilitate the work the line should make a right angle turn in front of the examiner in order to secure a good view of both sides and back with the least effort.

The examiner then proceeds in a systematic manner to examine the line as it approaches. Standing with the light falling over his shoulder he begins his study of the alien at about twenty feet distant. Beginning with the feet at that distance, as the alien draws near the eye gradually rises from the feet to the head without effort. The character of the gait or other defect of the lower extremities will attract attention such as flat feet, nervous disorders, deformities, abnormalities, joint diseases, or artificial legs. As the glance sweeps upward undue prominence of or about the groins may be noted, the hands as they furnish important evidence of the general physical development, diseases of the respiratory and vascular system, disordered or impaired nutrition, defective mentality, nervous, cutaneous diseases besides local defects and deformities. The abdomen noticed for undue protrusion, ascites, splenic enlargement, pregnancy and abdominal tumors in general. The chest for asymmetry, undue prominence, defective development and the back for evidence of spinal disease and deformity. The neck is surveyed for goitre, abnormal pulsations, enlarged glands, tumors and deformities. The

head is examined for abnormalities such as unusual shape deformity, disproportion, and asymmetry affecting the bones of the face and skull; this includes any signs of disease of the ears as well as the skin. The oral and ocular membranes act as an index for anaemia, while the scalp and beard are scrutinized for evidence of ringworm, favus or other infection. By this time the alien has arrived close enough for the eyes to be taken into close detail and the lids everted for the detection of trachoma.

A feminine voice may further confirm the suspicion of arrested sexual development which has been aroused by noting the absence of beard and the peculiar wrinkles about the upper lip, a tremulous voice often found in alcoholics, scanning speech or hoarseness make us at once turn off a case for more detailed examination.

Not only sight but the sense of touch and smell play a part. The hand against the forehead gives an idea of the presence of fever at the same time sight is taking in conditions about the mouth. Response to a simple question gives an index of hearing and mental reaction, while the sense of smell simultaneously may arouse suspicion of uraemia, ozaena, favus, foul discharge from ear, abscesses or ulcers concealed by clothing.

Associated with this the examiner acquires a habit of noticing unusual conduct, bearing, language, peculiar facial expression and emotional outbreaks. Febrile changes are constantly watched for, signs of exanthemata and in infants one of the most obvious signs of respiratory changes may be noted by watching the movements of the alae nasi muscles. Defective vision is often detected by squinting, a desire to keep in the proximity of accompanying persons, a tendency to look downward while walking, avoid the gaze of the examiner, indecision or confusion in the sense of orientation when obliged to make a sudden change in the direction of his course.

By the time the immigrant is face to face with the examiner a general impression has been formed and it has either been so favorable that the alien is passed at once or something may have been noted to cause his detention.

The above gives briefly a general idea as to what observation shows on the primary examination and the secondary examination is the regular medical procedure to confirm a diagnosis or pass the alien.

To the casual visitor it may seem a routine condition and tend to justify the criticism of a writer that I quote from a Boston newspaper. "The immigrants simply file past them and they look hard at them as hard as they can and that is about all they do. If they are looking for any particular one they switch him off for further examination and they do the same if their suspicions are aroused. They are really very clever at detecting skin and eye diseases and do their best work in that line. They don't see all and thousands get by them. Diseases like tuberculosis of the lungs are constantly coming in against the law; all except the very advanced cases getting in. Still more important are the diseases of the mind, the feeble minded and the insane which are rarely detected." Owing to the critic's lack of knowledge of the immigration law, lack of experience in the practical side of the examination and its results, the above is a good description of the impression made and is of about the same value as the opinion of the medical student who after attending a few large surgical clinics, said that all there was to surgery was "cut it off or cut it out." As matter of fact there is much more to it than the casual visitor ever sees unless he is willing to spend plenty of time in careful investigation of the subject from all sides.

A knowledge of racial types and their peculiarities is essential, for without this a great many normal persons would be detained, hence ethnology plays an important part.

Since the days of laboratory and other aids to diagnosis we have tended to lose sight of the value of observation and what it may tell us until we are reminded of it by some expert like the late Professor Fitz of Harvard. It is of interest to note that over seventy-five years ago Robert Ferguson in a lecture before the students of King's College, London, stated "That there is a right and wrong method of observing is evident since mankind has always observed but rarely discovered." In fact it can be safely stated that almost no grave organic disease can have a hold on an individual without stamping some evidence of its presence upon the appearance of the patient evident to the eye or hand of the trained observer.

It must be borne in mind that owing to certain limitations immigration inspection is a sieve and not a dam, also medicine is not a science like mathematics. It would be decidedly unfair to certify a person on suspicion, hence it is a wise provision in the regulations that calls for definite evidence and gives the alien the right of appeal. While to those that look on from the outside it may seem as if little is accomplished; if one considers the fact that the stream of men, women and children passing in line is really composed of a body of individuals from whom the physicians in the employ of the steamship companies have already endeavored to eliminate the physical and mental unfit, it may be a matter of surprise to know that about 1.5 per cent. of the total number of immigrants arriving at the ports of the United States have been certified for physical or mental defects that would place them in one of the classes which either rendered deportation mandatory or required the alien to submit satisfactory proof that his disability will not make him a public charge.

To show how experience in this work is necessary to avoid the mistake of confusing racial characteristics with pathological conditions some

conditions met with will be described in the following paragraphs.

It takes considerable experience to know what constitutes the healthy color in a given race. A healthy Gypsy might readily be suspected of having Addison's disease, a healthy Greek of suffering from malarial cachexia or malignant disease. A normal West Indian Negro sometimes has the peculiar pallor suggestive of tuberculosis and the temperate Alpine mountaineer often dilated capillaries resembling those seen in chronic alcoholics. Sea sickness may readily leave bad effects for some days and the pallor and weakness suggest some serious constitutional disease.

Pulsating blood vessels in the neck are often caused by fright increasing the heart action and it can be readily noted that all or nearly all immigrants pass before the doctor in a high state of nervous tension, for they believe that once by the medical officer the battle is nearly over. This is not their first medical examination. They have seen others weeded out before leaving, while during the voyage weird tales of all sorts have been poured into their ears as to what may happen with all the local color and exaggeration characteristic of human nature.

Irritation of the conjunctiva caused by certain occupations involving exposure to smoke, dust or heat, such as iron workers, bakers, coal miners and line workers may cause a chronic inflammation and scar formation of the lids simulating an old incompletely cicatrized trachoma.

The face of a muscular able-bodied Italian peasant often is so devoid of fat and muscle tissue that on first sight one would think that the whole body was thin and undeveloped. The complexion of the Slavish peasant woman would be suspicious of chlorosis if possessed by a Scandinavian or English woman of the same class. On the other hand the red cheek of the Scandinavian would arouse thought of a hectic flush if seen in the Polish woman.

The excitably of the southern Italian and the Hebrew are well known. It is easy to excite in them almost maniacal action. The stolidity and indifference of the Slav would suggest melancholia if presented by the Hebrew. The sanity of an Englishman would be questioned if on slight provocation he evinced the external manifestation of emotion that would occur in the Sicilian. The German girl takes her examination seriously and her sanity would at once be suspected if she saw the same reason for light remark and laughter as the girl from Ireland. Some races are extremely emotional, others slow; and unless the normal is known it is impossible to pick the abnormal. In short, in determining mental conditions by inspection the first essential is to determine the race or type of the individual and to have a good knowledge of his racial characteristics. To the trained examiner the facial expression, attitude, mannerism and dress convey an expression of understanding. It would be difficult for an examiner not familiar say with the Syrian peasant type to form any opinion of his mental calibre from his appearance or attitude alone. A few questions will determine reaction and orientation. If from this nothing is noted the alien may be allowed to pass, otherwise he is held for a more complete mental examination.

It is unpracticable under the present law and facilities to consider every alien a possible mental defective and subject him to complete examination unless on primary inspection there were some signs of mental disorder. With the feeble-minded, the facial expression and attitude is a valuable index except in the high-grade types where it is negligible and is then a matter of judgment and experience of the examiner (based upon the normal) to decide how much lower the suspect is in the mental scale, considering all the factors of race, previous environment and education.

Owing to the lack of agreement among experts as to where the normal ends, the mental problem is a difficult one. The term mental instability, psychopathic tendency or constitutionally inferior can be referred to a class whose mental organization is of the weakest, yet showing no definite mental symptom at present, would go on normally in primitive surroundings but on slight stress such as found in a new country with its disappointments, its strange language and customs become mentally disordered.

Investigators that have given careful study of the subject agree that the medical inspection is no farce. Examiners that have had years of experience in the service have seen a marked increase in efficiency due to experience and increased facilities. It is by no means perfect but is being improved as fast as Congress will grant authority and facilities. There are still many loopholes and any attempt to seal them is naturally fought bitterly by those interested in keeping an open gate.

Rarely are newspaper or magazine articles on the subject fact but rather sentimental fiction with just enough fact to give a foundation for a good story.

Every time a defective is admitted it is an inducement for many more to try. If the public were truthfully informed it would result in the country receiving a better physical and mental type of immigrant and in turn the immigrant would or could have better treatment and protection.

It has been estimated that out of the alien head tax of $4.00 about twelve cents pays the cost of the present inspection. If this is true the public treasury is certainly not being drained by the medical department.

The work is hazardous and requires men of good physique. Furthermore, they must be interested in the subject in order to pay close

attention to their work. In the busy season the constant standing and mental concentration tend to produce breakdown and there is always the chance of contracting contagious diseases.

PTOSIS—A CAUSE OF GYNECOLOGICAL FAILURE.

BY F. S. KELLOGG, M.D., BOSTON.

MANY patients continue to be sick after gynecological operations performed for their relief or cure. This is due to many well-known causes, perhaps the most potent being that much gynecology is done on patients who cannot or will not afford "after treatment," used as an all embracing term.

That ptosis unrecognized or untreated is often the cause of this failure to get results I feel sure.

Four cases seen in the last six months show this is so, even in good hands. Out-patient hospital cases show it more often.

CASE 1. Miss S., 25 years old. Stenographer. Operated three years ago. Complaint at that time, constipation and bloating, pain in back, dysmenorrhea, fainting between and with periods. Operator is one of New England's foremost gynecologists. Operation, D. and C. Appendectomy, resection cystic ovaries, ventral suspension. Result of operation: As before except that periods easier for several months, when they became as painful as before operation. Referred by family physician, with statement that case is very neurasthenic. Wishes to know if there is anything in pelvis to account for symptoms.

CASE 2. Mrs. K., 40 years old. Married, 2 children. Operated two years ago. Complaint at that time, nervous debility, backache, leucorrhea, constipation and indigestion. Operator one of Boston's foremost gynecologists. Operation, amputation of cervix. Since operation previous symptoms all worse; referred by physician with statement that he finds nothing wrong medically, that patient is neurasthenic, and complains constantly of soreness in the abdomen. Wishes to know if there is anything in pelvis to account for this.

CASE 3. Mrs. S., married 6 years; 27 years old. Five months after marriage consulted physician for pain in left lower quadrant, vaginal discharge, pain and burning on micturition. He told her the womb was tipped and said he replaced it. The pain continued, she became very constipated and "felt her food," so she consulted another physician. He told her she had "inflammation" and treated her for it three years; at the end of this time he felt he was not getting results and called in consultation a reputable and well-known gynecologist. He operated, D. and C., left salpingectomy, resection left ovary, appendectomy, and suspension. Result: Pain as before, constipation and gas worse. In 1912 she became pregnant and was delivered by operation of a living full-term child, the next day her cervix and perineum were repaired. Since the baby, which was followed by an afebrile puerperium, she has had her previous symptoms increasingly, has lost 25 pounds, and has been markedly tender in the lower quadrants, has had no coitus on this account. She is referred by her physician who wishes to know if what he finds in her pelvis accounts for the symptoms.

CASE 4. Mrs. H., married, 24 years old. Delivered by Caesarian section 18 months ago by well-known obstetrician in Boston. Indication, generally contracted pelvis. Since operation bowels have never moved without strong cathartics, has soreness in abdomen, bloats so that rarely can wear a corset. She returned to the obstetrician and was treated medically by him for some time, then went to three physicians in own district and had stomach washings, rectal washings, and bladder washings. Referred by last physician, who wishes to know if anything in pelvis accounts for symptoms and loss of weight. Suggests that gut may be adherent to uterus.

It is only fair to call these cases complete operative failures, save perhaps for the baby in case four. These patients felt they had not got their money's worth. They knew they were neurasthenics because many doctors had told them so, and they were skeptical of the medical profession. The "operative failure" who has had "neurasthenia" wished on her by some doctor is difficult to help.

These four patients had ptosis when I saw them. They had symptoms of ptosis when operated upon except the last, in which it subsequently went unrecognized by the operator Regarding the pelves—Case I. had a retroversion temporarily adherent recurring after her operation. Case II. had nothing except a beautiful new cervix. Case III. had a recurrent temporarily adherent uterus and tender vaults without masses. Case IV. had an uterus adherent to the lower end of a high Caesarian scar, pelvis otherwise negative. Case I. had uterus replaced and held with pessary after depletion; it helped the periods, nothing else. Case III. had the same; it helped the pelvic tenderness, nothing else.

They were relieved of all symptoms, including "neurasthenia," by mechanical support of the abdomen.

There seems to be some question among good physicians whether the disease ptosis exists. By the disease ptosis I mean dropping of viscera, especially the transverse colon, giving rise to intestinal stasis, "indigestion," sometimes gas formation. And gas stasis, giving rise clinically to bloating. It is not necessary in admitting this to admit the far reaching well-known conclusion of Metchnikoff and Lane of the influence of this sequence on other organs as a factor in the production of other diseases. To illustrate this skepticism: I had operated not long ago on a young woman with a membranous adhesion between ascending transverse colon, and omentum. She had resisted treatment at the hands of a

good medical man, together with mechanical treatment carefully carried out over a period of two months. X-Ray showed bismuth in the dilated ascending colon 30 hours after ingestion. Operation showed the adhesion and the ptosis precisely as the x-ray man had promised. The patient had lost 25 pounds in ten months. Though too recent to be sure of a cure, she has gained five pounds, eats well, feels well, and has good color. My etherizer met in the hall a medical acquaintance, an excellent physician, and spoke of the case in some detail. The excellent physician replied that he had doubts about *all* this visceroptosis business for he saw so many patients with ptosis without symptoms. I think, considering the mass of observation on the subject, and the therapeutic results in orthopedic hands that this is ultra-conservative. Valvular heart disease without symptoms is fairly common, I believe; it is common to have symptoms with valvular heart disease. So with ptosis, it occurs with and without symptoms.

Regarding the diagnosis it simply requires that the observer be looking for it. The appearance of the abdomen with gutters running down on either side from the ribs to about the level of the umbilicus, plus the symptoms specially bloating or a sense of bloating and soreness plus any, all or none of the four tender points, right lower quadrant, hepatic flexure, left lower quadrant, splenic flexure; and the x-ray will confirm it if one wishes. The condition if of long standing makes the patient thin so that the abdomen, especially in nullipara, is not necessarily protuberant and these cases oftenest escape detection.

The treatment of uncomplicated ptosis belongs by right to the orthopedic surgeon, and has been best described and carried out by him. A most striking therapeutic result is obtained in straight ptosis by the well equipped orthopedic emporium. There in addition to the mechanical support, the corset, the details of which they best understand, they command the means for teaching strengthening exercise and profitable posture. In short, any case of ptosis, certainly if the x-ray shows it free from bands, adhesions etc., not doing well in the hands of any other branch of the profession should have the final benefit of treatment in the hands of the orthopedic surgeon. I believe as well that this treatment will benefit many cases with apparent bands, membranes, etc., and think it should be given a fair trial before cutting operations are resorted to. It is not time lost because after cutting surgery it seems reasonable that a better permanent result will be obtained by orthopedic support than if this is neglected and the "orthopedic education" is better taught before operation than some weeks after it when the patient recovers sufficiently to make it possible.

It is not the purpose of this paper to consider the details of ptosis treatment, a matter already laid before the profession by far abler minds with far broader experience. It requires considerable study and much patience and fussing, especially when working with a cheap enough corset to make the treatment acceptable or possible to the patient who is "doctor-poor" from previous experience. Such a one will not have faith enough to pay $25.00 for a corset, certainly not at first.

It may be said in passing that skepticism with regard to the pathological entity of ptosis illustrated earlier, is nothing compared to that with regard to treatment by corset support among many physicians who have tried it. They say they have "thoroughly tried it out and there's nothing in it." Their methods of thoroughly trying it out develop on further questioning to about that of leaving the patient in a room with a corset, some very hygenic corset, and letting them get acquainted. Another method, somewhat better though still bad, is to ship the patient to a lady corset maker, who may or may not help, depending somewhat on the embonpoint of the individual, the fatter patient getting the better service because the cosmetic effect especially of the only just now dying style, and the hygienic necessity somewhat parallel. The thin ptotic has no chance in the world with her. The orthopedic surgeon, he himself, not even his trained corset maker or trained nurse, fits and adjusts his corsets with a definite object, and anybody else must do the same to get results. And a $3 or $5 corset made of relatively cheap, stretchable material will stop doing its work in 4 to 7 days after it has been fitted, due to the stretching in fabric and change in figure. After it is fixed it will do it again in ten days, and it will do it again and some more, and must be watched.

One other practical point in working with corsets deserves mention. As a rule prolapsed viscera are not attached to the abdominal wall, even on the inside, and pulling up an abdomen with the hand inside the corset with the patient standing, especially when the patient has dropped to 95 pounds and has no abdomen, does not raise prolapsed viscera. In a manner as breezy as the subject under discussion Codman under title "Our Little Balloons, Some Observations On Gas and Ptosis,"* seems to show that the viscera are toy balloons held down at different levels by strings, the mesenteries, but tending to float up, so that to get the intestines down where they do not belong one must invert the individual, and if the individual walks erect as is customary the balloons remain high in the abdomen as they should. The gist of this somewhat Shavian article seems to be that the orthopedic explanation of ptosis has sought lightning as a cause when the barn took fire from a cigarette in the stall. Be that as it may, the fact is that the toy-balloon of the ptotic be it excellently, as it sometimes is, or poorly, as the article above referred to sug-

* Boston Med. and Surg. Jour., Oct. 9, 1913, vol. clxix, No. 15, "Our Little Balloons. Some Observations on Gas and Ptosis," by E. A. Codman, M.D., Boston.

gests, equipped with gas, is invariably overloaded with sand ballast;—the practical point being that if you place the patient in high Trendelenburg and apply the support and teach the patient to do the same you will get results, otherwise you probably will not.

Nor is it the purpose of this paper to deal with the very suggestive subject of the effect of intestinal stasis on pelvic disease. Nor has it to do with the cases which have adhesions and come to abdominal section. It is to impress that one reason for some definite failures in gynecological surgery is untreated ptosis, and because an operation which promises to cure and leaves the patient as before, though the surgical result is perfect, creates a prejudice against not only the operator but his branch. It appears to me therefore, that a working knowledge of ptosis with its variations is a necessity for those who do gynecological surgery.

THE PHYSIOLOGIC COST OF INSUFFICIENT PROTECTIVE CLOTHING.*

BY G. W. FITZ, M. D., BOSTON.

THERE is perhaps no subject of such constant and vital interest, on which there are so many opinions vigorously supported, as that of clothing. As what we wear is a matter of daily choice, that we may adapt ourselves to the vagaries of weather and climate, and as each individual considers himself the ultimate judge of what constitutes comfort for himself under these varying conditions, the subject is of necessity clouded by a mass of personal, unscientific, more or less haphazard opinion. The chief popular attempt to mould this opinion has been made, not by hygienists nor by physicians, who are as rarely consulted upon this subject as upon the family diet, but by the manufacturers of special fabrics, who have bombarded the public with cleverly constructed statements of the vital superiority of their particular products. As a result of this, there are today a number of clothing cults, supported by this quasi-scientific commercial literature, advocating the exclusive use of wool, silk, cotton, or linen, in knit, mesh, or other forms of weave, and in varying weights.

In an attempt to analyze and explain the various features of personal comfort involved in the different materials and weaves, and to establish the functions of clothing, certain physiologists, notably Rubner, have made elaborate experiments. They conclude that the essential features of ideal underclothing lie in its ability to remove moisture rapidly from the surface of the body and, at the same time, to delay its evaporation at the outer surface of the clothing, in order to avoid chill. The ideal underclothing must further be sufficiently porous to give adequate ventilation to the surface of the body and must contain fibres sufficiently elastic to give a large air and moisture capacity, which they must retain even when wet, thereby avoiding clinging to the skin and loss of ventilation.

The material which in cool weather best meets these requirements in underclothing, they found to be that which Nature has developed in various forms, in her vast experimental laboratory, expressly for the protection of animal life, namely hair or wool; and its mode of manufacture to be the so-called tricot, or knit, weave. The objection to the practical use of wool which they recognize, is its first cost and its liability to be quickly ruined by shrinking when washed.

Next in value to wool, they found silk, which, although somewhat inferior to wool in certain characteristics, has the advantage of being an extremely agreeable and smooth fabric, which is not at all irritating to sensitive skins. The insurmountable objection to its general use is its very high initial cost and its lack of durability in the knit weave.

Cotton proved to be next in value to wool and silk. Cotton fabric however, is somewhat deficient in the essential characteristic of elasticity of fibre. Therefore, when used as underclothing, it has an inferior air and moisture capacity, and fails, even when dry, to conserve the body heat to the same degree as wool. When moist, its inferiority is considerably increased by the softening of its fibres and the consequent reduction of its air and moisture capacity; the ventilation of the skin, to which it tends to cling, is reduced, at the same time that the rapidity of evaporation from its outer surface is decidedly increased. The heat of the body is thereby dissipated so rapidly that chill often results.

Linen was found to be still less desirable than cotton, since it favors an even more rapid evaporation of the body's moisture and thereby greatly predisposes to chill.

The desirable weave for all of these materials, when used as underclothing, was proven to be the tricot or knit, because of the added elasticity and porosity it imparts to the fabrics. In the case of cotton, this weave contributes a firmness which somewhat lessens its tendency to cling to the skin and to lose its porosity when moist.

The open mesh weave Rubner found objectionable in direct proportion to the size of its holes, since it reduces the fabric's ability to absorb and remove from the skin its excess moisture.

We naturally turn from the conflicting and confused opinions of the laity with their vagaries of habit and standards of immediate personal comfort, and the conclusions of the physiologists, which are based largely upon the physical characteristics of clothing in their re-

* Read at International Congress on School Hygiene, Buffalo, August 25-30, 1913.

lation to the heat regulation of the animal body, to the experience of physicians, based upon the observation of the influence of clothing upon health. In this, we naturally expect greater unanimity of opinion through the generalization and elimination of individual peculiarities and the formulation of a consistent standard of clothing use from the standpoint of health.

Being unable to find any satisfactory expression of such medical opinion, I sent a questionnaire to several hundred of the most prominent medical practitioners of America, selected chiefly from Cattell's *American Men of Science*. Rather more than a hundred replies were received. Of these, forty odd, while expressing great interest in the subject, frankly acknowledged total ignorance of it, and admitted an attitude based wholly upon personal predilection, since they had paid no attention to the clothing habits of their patients. More or less complete replies were received from about sixty, and have been tabulated on the basis of positive statements only. Of these, thirty-six agreed that personal comfort was a guide to the kind and amount of clothing required. Thirty-four stated positively that cold hands, feet, nose and ears were reliable signs of insufficient clothing, barring the presence of chronic cardiac or other causative disease. Only eight considered cold extremities consistent with adequate clothing and normal health. Other criteria suggested by a few were general health, resistance to disease, weight and reaction to cold.

In the selection of materials for clothing, although there was not complete unanimity of opinion on the part of those who committed themselves, wool led by more than five to one in its favor. Twenty-seven claimed that at all ages in cool climates wool was a necessary protection. Only five claimed that it was totally unnecessary. Twenty-five considered it essential as underclothing, especially in childhood; twenty-eight considered it also essential as underclothing for old age. Twenty-seven made it essential as outer clothing for all ages. As a more or less complete substitute for wool in underclothing, sixteen favored cotton, three specifying cotton mesh; seven favored linen, four specifying linen mesh; nine favored silk; eight favored mixed wool and cotton.

In reply to the question as to the hygienic safety of the present light-weight winter clothing for women and children, thirty-seven condemned it as unsafe; four were in doubt; eleven approved of it. Among the deleterious effects stated to have been observed were an increased tendency to colds and minor illnesses, poor sleep, lowered intellectual efficiency, decreased growth and development. Twenty-two expected from it decreased, while two expected increased, resistance to disease.

In choice of room temperature, greater unanimity of opinion is apparent, in that only one called for a temperature above 73° F., whereas forty-one chose a range of 65° to 70,° with a marked tendency in favor of 67° to 68°. The remaining eighteen were non-committal, with the exception of four, who thought higher temperatures at times necessary, unless the great dryness of indoor winter air was neutralized by additional moisture.

The following diseases were recognized as having, in their experience, been associated with inadequate protective clothing: bronchitis, by 30; nasal catarrh, by 27; pneumonia, by 26; pleurisy, gastro-enteritis and rheumatism, by 22; nephritis and tonsillitis, by 19; tuberculosis, by 18; middle ear and antrum inflammation, by 16; catarrhal jaundice, gastritis, rheumatoid arthritis and imperfect nutrition, by 14; retarded growth, by 13; dyspepsia and neurasthenia, by 10; osteo-arthritis and villous arthritis, by 8. Thus many physicians are seen to recognize as results of under-protection by clothing, not only acute catarrhal troubles, but also remote and essentially chronic organic, joint, and nervous ailments, which, in their inception, may in no wise affect the individual's immediate sense of comfort and against which he may not therefore guard himself.

A large proportion of the prominent physicians who replied to my questionnaire would thus seem to be in agreement with the findings of the physiologists, that wool is the superior material for clothing and that it is a necessary safeguard of health.

Their conclusion would appear to be borne out by the practical experiences of men in the more trying branches of labor, where disability is quickly shown, as firemen on steamships and workers in foundries and other places in which perspiring men are exposed to cold drafts of air. I remember, for example, a foundryman coming to my clinic with a markedly painful spinal osteo-arthritis, who, when questioned as to his habits of clothing, replied that, when he went into the foundry, the workmen all advised him to wear wool underclothes and warned him that otherwise his back was sure to become crippled. Because of poverty and a large family, he wore heavy cotton instead, with the result of being permanently incapacitated for heavy work at the end of a few years. This is only one of many instances which have come under my observation and have convinced me of the causal relation between inadequate protection by clothing and remote ailments of rheumatoid or arthritic type, which are not generally recognized as being thus associated.

The deleterious effects of inadequate clothing are not confined to adults. There is a type of child, poorly nourished and generally underdeveloped in strength and endurance, with poor appetite and constantly subject to minor ailments, who is popularly diagnosed as having poor circulation because of habitually cold extremities. We often see in this class marvelous improvement as a result of changing to wool underclothing, sufficient in amount to keep the hands and feet warm. Unfortunately, the change

is often attributed entirely to the tonic medicine which the doctor usually gives at the same time.

Many persons, especially women, are content to go through life with cold extremities, accepting the popular verdict of poor circulation, because they experience no particular discomfort, on account of the essential exhaustion of the terminal sense organs for cold in the extremities. In this class we frequently find developed, usually after the years 30 to 35, many cases of painful joints, especially of foot, ankle, knee and hand. The joints, on examination, frequently show distinct enlargement, that is, are osteo-arthritic in nature. In some, the enlargement is very slight and its sensitiveness greatly in excess of that seemingly warranted by the physical condition. We find further many cases of nervous irritability, ranging from the "nervous stomach" to distinct and painful neuritis of persistent type.

This multitude of cases, such as painful joints in women and children, colic, especially in young children, nervous states seemingly obscure in their origin, malnutrition, sleeplessness, general irritability, and neuritis, which are ameliorated or even cured by a change to warmer clothing, constitute a mass of positive evidence which no amount of personal prejudice or negative experience would seem competent to overthrow. Negatively to argue that dozens of people are seemingly able to maintain their normal equilibrium for years in spite of inadequate clothing is far from proving either that they may not later pay with years of suffering, or that dozens of others do not pay earlier in life. It is the argument used to prove alcohol incapable of harm, because some drunkards live to be eighty.

That, notwithstanding this positive evidence, there yet exists today so much ignorance and conflicting opinion on the subject of under protection by clothing and its physiological cost (it will be remembered that out of over one hundred prominent physicians, nearly half expressed their ignorance of the subject) is undoubtedly due to our failure carefully to study the etiology of chronic diseases, and especially, to get adequate histories of the clothing habits of our patients. The situation is now further complicated by the great emphasis being laid upon the stimulating effect of cold and the miracles it performs, with the result that we are in danger of being swept off our feet in our indiscriminate use of this powerful agent. We are in danger of forgetting that, like most so-called stimulants, it has another and antagonistic side. Brief applications of cold, especially when alternated with heat, are marvelously stimulating to the nutritive processes and nerve control of the body. They train its heat-regulating apparatus to broaden the range of safe exposure to variations of temperature, and under such training, the body unquestionably becomes better able automatically to protect itself.

This use of cold as a stimulant and trainer of the automatic processes of the body is, however, a very different matter from the keeping of any part of the body constantly at a temperature below the normal of 98.5° F. Under these conditions, the delicately controlled heat-regulating mechanism at once acts in defence of the vital organs by partially excluding the blood from the extremities where it is being overcooled. The result is that the tissues of the extremities are kept in a state of anemia and chill. This means in a certain percentage of cases, but apparently not of necessity in all, that the nutritive conditions in bone, nerve, muscle, tendon and other tissue, are so changed that wholesome development and maintenance may be impossible. In this depressed condition, cellular activity is often so seriously impaired that the weak spot in the individual is made manifest, as in the form of overgrowth of tender bone around the joints, or of an abnormally irritable state of the nerve terminals and trunks. The cold, instead of being a stimulant, has now become a depressant of serious menace to comfort and health.

The normal warmth of the entire body, on the contrary, means the maintenance of cell activity at its maximum efficiency through the presence of a rich blood supply, and renders the body most resistant to disease.

It thus appears that each individual has to consider whether or not, through adequate clothing, he will insure himself against the risk of illness or of prolonged discomfort and inefficiency during the later years of his life. It would seem that the safest form of insurance had been shown by physiologists and physicians and by the practical experience of men under trying temperature conditions, to be wool clothing for cool weather, since by its use the body has been found to be fully protected. The expense of this insurance has by many been considered prohibitive, not because of its first cost, but because the life of the porous wool undergarment is so shortened by shrinkage in washing. This objection I have proved to be easily obviated. For the past ten years, my family and I have worn in winter pure wool unions, of varying weights, a form of garment which cannot be worn when even slightly shrunk. By using ammonia in wash water of blood temperature and a so-called wool soap and by avoiding rubbing except lightly with the hands, we have not been able to discover any shrinkage or loss of original softness and pliability. Garments originally bought large, of heavy weight and pure wool, have remained too large even after several years of use, and garments of exact fit have remained so. From the standpoint of economy, therefore, judged by its yearly cost as an insurance against financial loss through illness and inefficiency, knit wool underclothing must be considered remarkably cheap.

From the standpoint of the possible physiological cost of inadequate clothing in lowered vitality, illness, and inefficiency, as well as discomfort, we must consider it extremely fortunate that nature, by its ages of experimentation

to develop for animal life the best protection against wet and cold, has thereby provided the human animal with so adequate a protective material.

In view of the fact, however, that there is so much confusion in the popular mind on the subject of proper protection by clothing and so much neglect and difference of opinion on the part of physicians, and that the positive evidence of disability through underprotection, now at our disposal, is too isolated and fragmentary to be considered fully authoritative, it would seem that the great practical importance of the subject demands that it be more adequately studied in the future.

Since positive evidence of clothing effects upon patients under the observation of physicians furnishes the most valuable data for this study, I shall be very grateful to any physicians who are willing to coöperate with me by sending to me pertinent clinical reports of observed cases or the results of their observations along the lines indicated in the following questionnaire:—

1. Do you recognize as immediate or remote effects of insufficient clothing, any of the following ailments: Bronchitis, pneumonia, pleurisy, gastritis, nephritis, varicose veins, rheumatism, rheumatoid arthritis, osteo-arthritis, villous arthritis, neuritis, neurasthenia, dyspepsia, gastro-enteritis, catarrhal jaundice, nasal catarrh, tuberculosis, tonsillitis, middle-ear inflammation, retarded growth, imperfect nutrition?

2. Do you consider that wool must be used as protective clothing in the cool weather of temperate regions?

As underclothing in childhood, youth, middle age, or old age?

As outer clothing in childhood, youth, middle age, or old age?

3. What do you consider an adequate substitute for wool in protective clothing, as underclothing? As outer clothing?

4. What do you consider the best tests of sufficient protection by clothing?

Are habitually cold hands and feet, nose and ears, consistent with adequate protection?

5. Do you consider the present underprotection in winter of the chests and extremities of women and children as hygienically safe?

What results therefrom have you already noticed?

6. In homes, schools, etc., during winter months, should the temperature be maintained at summer heat, 73°-77°, with indirect ventilation, and the occupants be dressed accordingly? or,

Should the temperature be maintained at or below 70°, with the addition of direct ventilation, and the occupants be dressed warmly enough to insure warm extremities?

FRACTURE OF THE CLAVICLE.

BY F. E. PECKHAM, M. D., PROVIDENCE, R. I.

IN THE BOSTON MEDICAL AND SURGICAL JOURNAL, Vol. clxvi, No. 21, pp. 777, 778, May 23, 1912, I published a method of treating fractures of the clavicle, which has since proved very efficient. Like all methods of holding a fracture, however, the details must be accurately carried out, each individual case must be treated by itself, and the mechanics made to accomplish the results.

To recapitulate, by means of webbing, (the correct width for the individual case), straps are made with whalebone placed in pockets running transversely and then the whole covered with cotton flannel. These straps go round the shoulders in such a way that the pull across the back draws them sharply backward. In order to accomplish this, the straps must be kept at the tips of the shoulders. See Figs. 2 and 3. When this pull backward is exerted at the tips of the shoulders, the fragments of a fracture of the clavicle are drawn out to length. Then, if this adjustment is continued, union will take place.

It seems to be the custom of the general practitioner as well as the general surgeon to put up such a fracture with a Velpeau bandage with the humerus strapped back, the idea being that strapping back the humerus holds the shoulder back, and that the Velpeau holds it up, and hence in position. It is commonly said also, that these fractures do well anyway, so that they get very little attention. If all the cases put up in this way were x-rayed, many would be found in which the apposition would not be very good, and in the case of women, would mean quite a callus formation, which would be very objectionable in evening dress.

To prove the efficiency of this method of treatment, a recent case will be reported.

This patient had suffered from a fractured clavicle seven and one-half weeks before consulting me. The shoulder had been treated by the usual bandaging, and the x-ray (see Fig. 1) shows the condition it was in, with the fragments riding by. The picture shows no callus formation and there was tenderness on pressure at the point of fracture and also on motion whether active or passive. By grasping the fragments between the fingers, no motion was elicited with a moderate amount of force. To loosen up the fracture, the knee was placed between the scapulae behind, the shoulders were then grasped firmly and forcibly pulled backward against the knee as a point of resistance. Then the fragments were grasped firmly with the fingers and manipulated, using as much force as possible. This hurt some, but no anesthetic was used. Then the straps were applied as shown in photograph. (See Figs. 2 and 3.) Then manipulation was made every day and the straps tightened to correspond to the gain. At the end of a week, or eight and one-half

FIG. 2.
Shows anterior view of strapping.

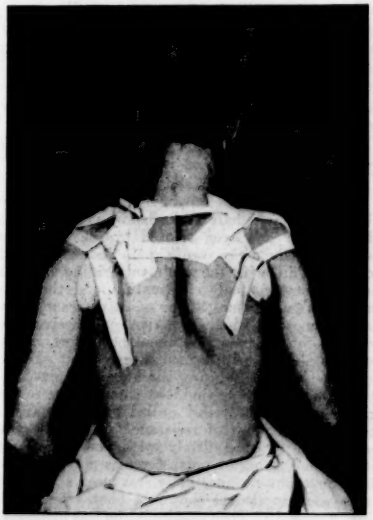

FIG. 3.
Shows posterior view of strapping.

weeks from the fracture, the x-ray showed good alignment, and the shoulder, which before was dropping, is now up to level. Manipulation ceased and the picture, ten and one-half weeks from the accident, shows the position and with callus formation (See Fig. 4.) Also this callus formation is only moderate and in no way does the so-called "bunch" of callus exist.

If such a result can be obtained in a fracture already seven and one-half weeks old, the possibility of duplicating it in a fresh fracture would seem to be good.

Medical Progress.

A REVIEW OF THE PROGRESS IN PATHOLOGY FOR 1913.

BY S. B. WOLBACH, M.D., BOSTON,

Assistant Professor of Bacteriology, Harvard University Medical School.

(*Concluded from page* 613.)

AMEBIC DYSENTERY.

RECENT work by Craig (War Dept., Office of the Surgeon-General, Bull. No. 2), (*Journal of Infectious Diseases*, Vol. 13, No. 1), and Darling (*Southern Medical Journal*, Vol. 6, No. 8) show that the two supposedly distinct species of parasitic ameba, entameba histolitica and entameba tetragena are identical. Entameba coli is not pathogenic. There is not sufficient evidence at present to prove that any of the amebae that have been cultivated are pathogenic to man.

Walker and Sellards (*Philippine Journal of Science*, Section B, Vol. 7, No. 4) also insist upon the identity of entameba histolitica and entameba tetragena. They present also what is perhaps the most important etiological study of amebic dysentery that has been made. Sixty feeding experiments were made upon man with different species of amebae and entamebae. Their results show that none of the amebae and entamebae, which may be cultivated on artificial media, are capable of producing dysentery in man. The cultivated amebae are incapable of living parasitically in the intestinal tract of man. When ingested, they may encyst and pass through the stools, whence they may be recultivated. Entameba coli, however, does multiply in the intestinal tract, but does not produce disease, and this fact was proved by an experiment in which twenty men ingested cultures of entameba coli. Entameba histolitica when given to man does produce dysentery. Out of twenty men who ingested material containing this organism, eighteen showed multiplication of the organism in the intestine, and of these eighteen, four developed entamebic dysentery. The incubation period was in the respective in-

stances, 20, 57, 87 and 95 days, giving an average of 64.8 days. It was also possible to prove conclusively that the forms described as entameba tetragena might occur exclusively in the stools of men who had ingested entameba histolitica only, and that motile entameba histolitica might occur exclusively in men who had ingested only tetragena forms. Other evidence is given which convincingly proves that tetragena cysts are developed in the life cycle of entameba histolitica. This work is of tremendous importance in that it establishes the pathogenicity of only one type of the ameba found in human stools. It makes a positive diagnosis possible,

FRACTURE OF THE CLAVICLE—PECKHAM.

FIG. 1.
Shows the fracture seven and one-half weeks from the accident. The fragments are riding by, and there is no callus formation.

FIG. 4.
Shows the fracture ten and one-half weeks from the accident.

flasks containing the medium with valves and secured anaerobic conditions by exhausting the air and replacing with hydrogen repeatedly. The morphology of the parasite is described and illustrated as minute chromatoid bodies which are similar to those described by a long list of observers in vaccine and smallpox pustules. The cultures and sub-cultures were inoculated into calves and produced vaccine vesicles. The name *Microsoma vaccinae* is given.

Noguchi and Cohen (*Journal of Experimental Medicine*, Vol. xviii, No. 5) using the spirochete culture technic, claim to have cultivated an organism from trachoma. The organism cultivated resembles the trachoma bodies found in human lesions, and there is a morphological sequence in the cultures similar to that observed in tissues, namely, initial bodies, lanceolate or ovoid in shape and occurring in pairs, groups and rosettes, and later extremely minute, round or ovoid granules occurring in pairs and masses. Inoculation experiments on monkeys were negative; a transient papillary conjunctivitis lasting about one week was produced in some cases. Trachoma bodies were not found.

BERI BERI AND SCORBUTUS.

Holst and Frölich (*Zeit. f. Hyg.* Bd. 75, Heft 2) have extended the work which was abstracted in the *Review of Pathology* last year, for the purpose of determining the nature of the anti-scorbutic substances and their preservation chiefly with the nature of beri beri and the substances which prevent the disease—the vitamines. He finds that the vitamine fraction from yeast is made up of three substances; one of the formula $C_{24}H_{19}O_9N_5$; another $C_{20}H_{23}O_9N_5$ and nicotinic acid. From the vitamine fraction of bran, two substances have been isolated, $C_{28}H_{20}O_9N_4$ and nicotinic acid. A table is also given of the composition and value of the various purine, pyrimidin and nuclein derivatives with their allied forms of allantoin and hydrantoin. He finds that those substances were the most active which in composition most nearly resembled vitamines.

STREPTOCOCCUS AND PNEUMOCOCCUS.

Rosenow (*Journal of Infectious Diseases*, Vol. xiv, No. 1, p. 1) describes with convincing detail

weeks from the fracture, the x-ray showed good alignment, and the shoulder, which before was dropping, is now up to level. Manipulation ceased and the picture, ten and one-half weeks from the accident, shows the position and with callus formation (See Fig. 4.) Also this callus formation is only moderate and in no way does the so-called "bunch" of callus exist.

If such a result can be obtained in a fracture already seven and one-half weeks old, the possibility of duplicating it in a fresh fracture would seem to be good.

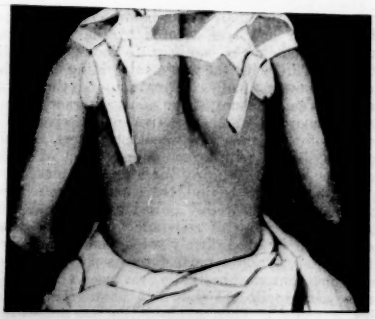

FIG. 3.
Shows posterior view of strapping.

Their results show that none of the amebae and entamebae, which may be cultivated on artificial media, are capable of producing dysentery in man. The cultivated amebae are incapable of living parasitically in the intestinal tract of man. When ingested, they may encyst and pass through the stools, whence they may be recultivated. Entameba coli, however, does multiply in the intestinal tract, but does not produce disease, and this fact was proved by an experiment in which twenty men ingested cultures of entameba coli. Entameba histolitica when given to man does produce dysentery. Out of twenty men who ingested material containing this organism, eighteen showed multiplication of the organism in the intestine, and of these eighteen, four developed entamebic dysentery. The incubation period was in the respective in-

stances, 20, 57, 87 and 95 days, giving an average of 64.8 days. It was also possible to prove conclusively that the forms described as entameba tetragena might occur exclusively in the stools of men who had ingested entameba histolitica only, and that motile entameba histolitica might occur exclusively in men who had ingested only tetragena forms. Other evidence is given which convincingly proves that tetragena cysts are developed in the life cycle of entameba histolitica. This work is of tremendous importance in that it establishes the pathogenicity of only one type of the ameba found in human stools. It makes a positive diagnosis possible, and it will prevent needless treatment of persons having non-pathogenic ameba in their stools, while affording absolute indications for the treatment of ameba carriers.

CULTIVATION OF NEW PARASITES.

Noguchi (*Journal of Experimental Medicine*, Vol xviii, No. 3) reports briefly the cultivation of the parasite of rabies. The method employed is similar to that used for the cultivation of the relapsing fever spirochete. The culture medium consists of sterile human ascitic fluid containing a fresh piece of sterile rabbit's kidney and covered with paraffin oil. The parasites are described as minute, granular and pleomorphic chromatoid bodies. Other forms, simulating negri bodies were found. These cultures were capable of producing rabies in dogs, rabbits and guinea-pigs.

Fornet (*Berliner Klin. Woch.*, Bd. 50, p. 40) reports the cultivation of the parasite of vaccinia. Raw vaccine lymph is made sterile by shaking with ether; this usually requires about twenty hours of continuous shaking. The ether does not diminish the virulence of the vaccine. After the material has been proved to be sterile for bacteria, the ether is removed by evaporation in an exhausted chamber. The bacteria-free virus is inoculated into a medium composed of one-third beef serum or ascitic fluid and two-thirds sugar bouillon. Growth takes place under anaerobic conditions. Fornet equipped glass flasks containing the medium with valves and secured anaerobic conditions by exhausting the air and replacing with hydrogen repeatedly. The morphology of the parasite is described and illustrated as minute chromatoid bodies which are similar to those described by a long list of observers in vaccine and smallpox pustules. The cultures and sub-cultures were inoculated into calves and produced vaccine vesicles. The name *Microsoma vaccinae* is given.

Noguchi and Cohen (*Journal of Experimental Medicine*, Vol. xviii, No. 5) using the spirochete culture technic, claim to have cultivated an organism from trachoma. The organism cultivated resembles the trachoma bodies found in human lesions, and there is a morphological sequence in the cultures similar to that observed in tissues, namely, initial bodies, lanceolate or ovoid in shape and occurring in pairs, groups and rosettes, and later extremely minute, round or ovoid granules occurring in pairs and masses. Inoculation experiments on monkeys were negative; "a transient papillary conjunctivitis lasting about one week was produced in some cases. Trachoma bodies were not found.

BERI BERI AND SCORBUTUS.

Holst and Frölich (*Zeit. f. Hyg.* Bd. 75, Heft 2) have extended the work which was abstracted in the *Review of Pathology* last year, for the purpose of determining the nature of the anti-scorbutic substances and their preservation. They found that heating destroyed the anti-scorbutic properties of cabbage and milk, while on the other hand, drying in a vacuum did not destroy the anti-scorbutic substances. They also found that acid plant juices preserved their anti-scorbutic property after heating. The anti-scorbutic substances can best be extracted by acid solutions, and these substances may be extracted and preserved in 80% alcohol containing 1% of citric acid. On the exact nature of the anti-scorbutic bodies they have nothing to say.

Vedder and Willliams (*Philippine Journal of Science*, Section B, Vol viii, No. 3) report a large number of experiments to determine the composition, preparation and methods for isolating protective substances against beri beri from rice polishings. They have confirmed Funk's observations by isolating a crystalline base (Funk's vitamine) from rice polishings by Funk's method. This base promptly cured fowls suffering from experimental beri beri or polyneuritis. In addition to Funk's vitamine they have isolated two groups of substances, purine bases and choline-like bases which are capable of partly or wholly protecting fowls fed on polished rice against poly neuritis, but these substances are incapable of curing fowls that have the disease.

Funk (*Ergebnisse der Physiologie*, Vol. xiii). This paper extends through two numbers of this journal and is very comprehensive. It deals chiefly with the nature of beri beri and the substances which prevent the disease—the vitamines. He finds that the vitamine fraction from yeast is made up of three substances; one of the formula $C_{24}H_{19}O_9N_5$; another C_{29} $H_{23}O_9N_5$ and nicotinic acid. From the vitamine fraction of bran, two substances have been isolated, $C_{28}H_{20}O_9N_4$ and nicotinic acid. A table is also given of the composition and value of the various purine, pyrimidin and nuclein derivatives with their allied forms of allantoin and hydrantoin. He finds that those substances were the most active which in composition most nearly resembled vitamines.

STREPTOCOCCUS AND PNEUMOCOCCUS.

Rosenow (*Journal of Infectious Diseases*, Vol. xiv, No. 1, p. 1) describes with convincing detail

the modification of streptococci in cultures, so that ordinary hemolytic streptococci were changed into types identical with streptococcus viridans, which is the type so commonly found in endocarditis cases. Further modification was secured by repeated passage through animals until the cultures had assumed all the characteristics of the pneumococcus. Rosenow believes that he has secured a genuine transmutation from streptococcus to pneumococcus. He has also succeeded in bringing about the reverse process. Every possible immune test was done to control the morphological and cultural changes. The acquisition of new immune properties with change of cultural characteristics is particularly suggestive and important.

While Rosenow's work in many ways is consistent with observed facts and would explain the large number of types of streptococci which can be distinguished culturally, and although it bears every earmark of honest purpose and accuracy, the conclusions are so remarkable that confirmation must be obtained before it will be generally accepted.

Floyd and Wolbach (*Journal of Medical Research*, Vol. xix, No. 3, p. 493) have published a preliminary report of the differentiation of streptococci, based upon a study of 147 cultures. They find, in substantiation of Gordon and Winslow, that it is possible, by cultural tests, to separate streptococci from human sources into six main divisions, and that there is a certain definite relationship between the character of the cultures and the nature of the pathologic process and prognosis. The validity of the grouping was supported by agglutination and complement-fixation tests.

Agglutination and complement fixation tests would indicate that the differences in immune reactions are found with differences in cultural characteristics, and if the latter can be acquired and lost, by change of conditions, it is quite probable that the former may vary accordingly. This is what Rosenow claims to have done experimentally.

ACID AGGLUTINATION OF BACTERIA.

During the last few years, considerable attention has been paid to the acid agglutination of bacteria. Briefly expressed, the term means the precipitation of bacteria from suspensions by various degrees of acidity. The acidity is expressed in terms of hydrogen ionization. The phenomenon may be elicited by inorganic acids and bears some relation to the precipitation of colloid solutions by electrolytes. It was supposed that the method would be of value in the differentiation of bacteria. Recent papers, however, by Sgalitzer (*Zeit. f. Hyg.*, Bd. 76, Vol. 2) and Gillespie (*Journal of Experimental Medicine*, Vol. xix, No. 1) show that the reaction cannot be made specific for different strains of organisms. The paper by Sgalitzer is very comprehensive and deals with a variety of organisms of the colon typhoid and cholera groups. Gillespie's paper concerns the acid agglutination of pneumococci only. The conclusions to be drawn from these papers as to the value of this method is that it will not serve for the identification of organisms for the purposes of diagnosis. It has some value, however, as a method of differentiation between closely allied organisms, in that these may be precipitated by different degrees of acidity.

EXPERIMENTAL NEPHRITIS.

As in previous years, the large proportion of the work of those engaged in experimental pathology has been directed towards the kidney. There has been little change in the character of the work done, and it consists mainly in the study of elimination of certain substances by the kidney, or the retention of others in the blood, after the establishment of renal lesions. The discovery by Underhill (*Journal of Biological Chemistry*, Vol. xii, p. 115) that the subcutaneous injection of sodium tartrate in rabbits and dogs would produce marked degeneration of the tubular epithelium of the kidneys, has stimulated some new work, and a repetition of older work with this form of experimental nephritis.

Underhill, Wells and Goldschmidt (*Journal of Experimental Medicine*, Vol xviii, No. 4) found that sodium tartrate when introduced subcutaneously into rabbits does not appear in the urine, and conclude that the disintegrative influence of the salt upon the tubules is sufficient to account for the failure of the salt to be eliminated. They could find no lesions of the glomeruli. A fairly extensive research by the same authors upon rabbits seems to show that the tartrate acts specifically upon the convoluted tubules of the kidney. To produce a marked effect it is necessary to give the salt subcutaneously; when given by mouth, the lesions are slight. The effect is most marked when fasting animals are used. The administration of alkali in the form of sodium carbonate, acetate or citrate during the state of fasting permits a greater elimination of urinary constituents during tartrate nephritis, and histologically there is some evidence that the alkali modifies the lesion. In a third paper in this same number these authors find that there is a marked diminution in nitrogen elimination, as determined by the effect upon the urine of injecting urea. On the other hand, sodium chloride is rapidly eliminated. In the light of the histological findings, the results are interpreted to mean that chlorides and water are passed through the glomerular mechanism, while urea becomes a urinary constituent by way of the convoluted tubules.

Pearce and Ringer (*Journal of Medical Research*, Vol. xxix, No. 1) noted exudative lesions in the glomeruli in tartrate nephritis in dogs, in addition to the severe lesions of the tubules. Pearce (*Journal of Experimental Medicine*, Vol. xviii, No. 2) makes a further report on the kid-

ney lesions produced by injection of rattlesnake venom, first described by him in 1909. The type of lesion is an acute exudative glomerular process. It was impossible to reproduce the subacute and chronic type of glomerular nephritis as seen in man.

Karsner and Denis (*Journal of Medical Research*, Vol. xix, No. 3) were unable to produce similar lesions in cats by the use of rattlesnake venom. In nephritides produced by hemolytic immune serum, arsenic, diphtheria toxin and tartaric acid, they showed that there is a demonstrable accumulation of nitrogen in the blood. The most marked results were obtained in the case of tartrate nephritis. In another paper, in this same number, they showed that in the subacute or chronic nephritis produced by repeated injections of uranium nitrate, there is an increase in the accumulation of non-protein nitrogen in the blood. However, with the subacute form of nephritis produced by diphtheria toxin injections, there is only a temporary or slight retention of nitrogen.

Other papers dealing with the function of experimentally diseased kidneys are those by Kraus (*Arch. of Internal Medicine*, Vol. xi, p. 613) and Frothingham, Fitz, Folin and Denis (*Arch. of Internal Medicine*, Vol. xii, p. 245). Both papers deal with uranium nephritis. Kraus found that creatinin excretion is diminished and uric acid excretion is increased in acute uranium nitrate nephritis. Creatinin injected in normal dogs is excreted "in toto," but if injected in uranium nitrate nephritis, it causes a decreased excretion of the normally occurring creatinin, uric acid, chlorides and water, and may cause death. The injection of creatinin in subacute uranium nephritis produces no effect.

The latter authors studied the relation between non-protein nitrogen retention and phenolsulphonephthalein excretions in renal uranium nephritis. They found that there was a retention of phenolsulphonephthalein with nitrogen retention so that the diminution of this substance in the urine is an indication of the retention of nitrogen and the degree of nephritis. They make, however, the important observation that the amount of phenolsulphonephthalein in the urine indicates the renal function at the moment, while the amount of non-protein nitrogen and urea in the blood is rather a measure of an accumulated difference between the amounts of waste nitrogen produced in the metabolism and the amount eliminated by the kidneys. The time element, therefore is an important factor in the test.

Rowntree, Fitz and Geraghty (*Arch. of Internal Medicine*, Vol. ii, p. 121) have made an experimental study on dogs to determine the effect of chronic passive congestion on the function of the kidney. The method consisted of applying constricting bands about the renal vein or the vena cava, above the entrance of the veins. The tests, which were adequately controlled, consisted in the study of the elimination of phenolsulphonephthalein, lactose, salt, potassium iodide and water. Lactose excretion is the first to become affected by increasing grades of chronic passive congestion; then excretion of salt and iodide; lastly that of phenolsulphonephthalein. The phenolsulphonephthalein test gives the most reliable information concerning the decrease of renal insufficiency, and decrease in the phenolsulphonephthalein excretion always means severe lesions and usually death. On the other hand, marked delay in the excretion of lactose, iodide and salt may occur with a normal phenolsulphonephthalein output. Lactose is the most delicate test for renal involvement, although it is of least prognostic importance.

Christian and O'Hare (*Journal of Medical Research*, Vol. xxviii, No. 1) describe the glomerular lesions produced by the injection of uranium nitrate. A variety of types are encountered, from the appearance of hyaline droplets in the capillary walls, to thrombus, hemorrhagic exudation, edema and even proliferation of the capillary epithelium.

O'Hare (*Arch. of Internal Medicine*, Vol. xii, No. 1) was unable to produce marked glomerular lesions in the kidneys of dogs, although the tubules were markedly affected. The only glomerular lesion he was able to produce by injections of uranium nitrate was that of hyaline droplet formation in the capillary tufts. Another paper by the same author in this number records experiments where uranium nitrate and Bacilli coli communis were injected into the same animals. The method employed varied in the individual animals. The bacterial cultures and drug in some instances were injected simultaneously, and in others at alternate intervals of varying lengths of time. By this method, chronic lesions were produced which simulate closely those in chronic interstitial nephritis in man.

MacNider (*Journal of Medical Research*, Vol. xxviii, No. 3) studied the effects of different anesthetics upon the kidney in acute uranium nephritis. Dogs were employed and the anesthetics used were mixtures of chloroform and alcohol and ether accompanied by subcutaneous injections of morphin. Anesthetics increased the severity of the changes produced by uranium nitrate. The chloroform-alcohol anesthetic (Gréhant's anesthetic) produced a more deleterious effect than ether and morphin.

Walker and Dawson (*Arch. of Internal Medicine*, Vol. xii. No. 2) have studied the effect of diuretic drugs on the lives of animals with severe acute uranium nitrate nephritis. Rabbits were employed and the results indicate that the diuretic drugs theocin, caffein and potassium acetate shorten the lives of rabbits having severe acute renal uranium nephritis. Spartein sulphate in some instances shortens the life of experimental animals, but is not as detrimental as the other drugs. Water in large amounts was also found to be detrimental in some cases. The

general conclusions are that diuretics are probably contraindicated in acute, severe nephritis in man, because in animals they do shorten life.

Mosenthal and Schlayer (*Deut. Arch. f. Klin. Med.*, Bd. 3, Nos. 3 and 4) have investigated the element of fatigue to diuretics, evidenced by kidneys diseased through chromium and uranium injections. In normal animals they found that repeated injections of salt give no evidence of renal fatigue, either in affecting the volume of urine excreted or the vascular response of the kidney as indicated by changes in the volume, registered by means of the oncometer. Repeated injections of caffein did give evidence of fatigue in that the maximum result was produced by the first injection. Subsequent injections produced a steadily decreasing volume of urine and sodium chloride content. The elimination of sodium chloride simultaneously injected diminished even more rapidly than the volume of urine. The behavior of the kidneys in these two forms of nephritis vary according to the stage. In the early stages of the nephritis produced by chromium, the injection of salt acted as a strong diuretic, while caffein decreased the amount of urine; in uranium nephritis the reverse was true. In chromium nephritis injections of salt acted as a strong diuretic, while caffein decreased the amount of urine, and this action was most marked when the diuresis produced by salt was at its maximum. On the other hand, in uranium nephritis, repeated injections of salt did not produce diuresis, but steadily diminishing amounts of urine, indicating fatigue. Injections of caffein greatly increased the amount of urine from the fatigued kidneys. No explanation is offered for the difference in these results.

Longcope (*Journal of Experimental Medicine*, Vol. xviii, No. 6) finds that the repeated injection of small doses of foreign protein, horse serum and egg white in dogs, cats, rabbits and guinea-pigs that have been sensitized to these products causes injury to the cells of various organs and tissues, with resulting, demonstrable inflammatory reactions. Among these changes, there develops in dogs and rabbits a well marked nephritis affecting the epithelium of the loops of Henle and the collecting tubules, and less frequently of the convoluted tubules. Lesions in the glomeruli are produced in all of the animals used, although these changes were slight and described as congestion and swelling and probably proliferation of the capillary epithelium.

LOS ANGELES OBSTETRICAL SOCIETY.—The Los Angeles Obstetrical Society was inaugurated March 25, 1914, with a membership of forty-seven. The Society is limited to fifty members and there is already a waiting list. The officers are Dr. Titian J. Coffey, president, and Dr. Geo. E. Malsbary, secretary.

Reports of Societies.

BOSTON SOCIETY OF PSYCHIATRY AND NEUROLOGY.

MEETING HELD AT THE BOSTON MEDICAL LIBRARY, JANUARY 7, 1914.

D. H. FULLER, M.D., Secretary.

DR. P. C. KNAPP read a paper entitled,

THE TREATMENT OF CASES OF MENTAL DISORDER IN GENERAL HOSPITALS.*

DISCUSSION.

DR. F. C. RICHARDSON: In the hospital with which I am connected there have been, in addition to the various deliria, not a few cases of true psychosis as well as many borderline conditions. As is the custom in most general hospitals, these cases have been cared for with inadequate means, and, I fear, insufficient knowledge.

An effort has been made to coöperate with the Westborough Hospital for the Insane in an exchange of nurses, so that the general hospital nurse may in a few weeks learn something of tube feeding, simple restraint, etc. It must be said, however, that our hospital executives object to this plan on the ground that nurses from hospitals for the insane are, as a rule, of distinctly inferior grade to those of our training school, and are apt to act as an unfavorable influence. On the other hand, it is found that comparatively few of our general nurses wish to submit to residence in the hospital for the insane. These facts point directly to the necessity for raising the standard of nurses for the care of the insane, and, while it is perhaps foreign to the subject under consideration, I may say that in my opinion this matter demands immediate and serious consideration by those in authority.

The advantages to the patients and to the attendants of keeping borderline and doubtful cases in the general hospital are obvious; and means for the proper care of such should be provided by every superintendent. Such provision is made in the neurological department of the Evans Memorial, where patients are kept under observation until definite decision can be arrived at. Such appliances as the camisole, stout restraining sheets, and equipment for giving the prolonged warm bath, sprays, douches, etc., enable us to feel justified in retaining these patients for a reasonable length of time, and thus saving them, perhaps, from the undesirable suspicion of having once been insane.

Neurologists having service in general hospitals have a right, it seems to me, to demand proper facilities for at least the temporary treatment of such mental cases as come under their care.

DR. W. J. BRICKLEY: There are about 40,000 patients a year, of all diagnoses, treated at the Haymarket Relief Station and, naturally, we receive many mental cases. We examine and treat them all for a time, and dispose of them as their needs require. They are brought there because this general hospital is convenient and the necessary examination can be quickly made. To refuse to ad-

* See page 637.

mit and treat such patients would work a hardship because of the delay in getting them to mental hospitals, which are usually situated at a distance from the center of the community and those citizens and the police who present them to us. The general hospital can assort the types of mental cases into the temporary as alcohol and hysteria, or rapid course cases as delirium tremens and toxemias, and the slower course cases, as general paralysis, dementias, etc. Everybody is willing, even eager, to have such cases enter a general hospital. No time is lost in obtaining a correct diagnosis and in starting treatment. In Haymarket we have these cases thrust on us and we must care for them. Most of our mental cases are due to the use of alcohol. Thus we have treated about 200 cases of delirium tremens this year. These are very hard problems for a general hospital. Dr. Knapp has spoken of the advantages of hydrotherapy and plenty of attendance. In my place we have no apparatus for hydrotherapy and have a scarcity of attendants. Therefore we do the best we can under the circumstances imposed upon us. I do restrain patients; I do give drugs, and I give enough of either, or both, to get results. Surrounded as our hospital is by busy streets, any patient who passed through our doors would be lost in thirty seconds. We have no extensive grounds with surrounding walls. Yet we have had only two patients escape and one who broke a leg by jumping from a window,—these during the past three years. This means eternal vigilance.

I know that hydrotherapy and individual care, with freedom from restraint, is best for the delirium tremens patient. Especially is restraint bad in the early phases, when the patient is promptly made worse by it; but lacking an adequate equipment, we have to resort to it. I have noticed that the delirium tremens cases that are almost well make good nurses for the sick delirium tremens cases. The convalescent delirium tremens cases are repentant and only too glad to assist in ward work, or in quieting and watching the delirious ones. In fact, they, being dull witted, are more patient than some orderlies would be. Thus the convalescents have the benefit of some simple employment, the sick are benefited and the hospital expense is cut down. This last leads me to a new phase of the subject. Dr. Knapp is a visiting physician and treats or orders treatment. The executive of the hospital is the one who must furnish the means of treatment. The executive cannot grant the demands of the visiting physician, at times. These mental cases, more especially the acute manias, are costly to treat. They are destructive and require a larger nursing force, etc.; they are a nuisance and a menace in a general ward. It is the executive who has to prevent or to explain the escape or injury of these mental cases,—not the visiting physician. As an executive as well as a treating physician, I know whereof I speak, when I assure you that the mental cases are the worst class to treat in a general hospital. None the less, I believe it to be the duty of the general hospital to receive and care for, temporarily, the sudden onset mental case. I believe that they should be under the care of neurologists; that, should they remain mental, they should stay in a general hospital only a short time,—weeks.

DR. J. J. THOMAS: I have very little to add to the interesting paper that Dr. Knapp has given us tonight, except to corroborate what he has said; and my experience with the service, during the half year in which it has been in my charge since it was established, has not differed essentially from what he has told us. The excited cases, which, of course, are the most difficult to handle with the facilities at our disposal, have not been a large proportion of the mental cases which have come to us. By a fortunate chance, what accidents have happened during my term of service have been upon other services than mine,—medical or surgical. By the use of hot packs and extra nurses, which the administration has always given on request, we have overcome some of the deficiencies of facilities. After all, however, these excited cases have been a small number of the whole, and I consider much more important the care of other cases, where the symptoms were distinctly mental, and the making possible, by this continued observation, the proper disposal of these cases. Many have recovered in a short time in the wards, either entirely, or so that they could be sent to the care of their relatives; others have been committed and still others sent to institutions like Tewksbury. Without this opportunity for study, I feel sure that many of these cases would not have been handled as well as we were able to do it. Other cases which were committed, I feel certain, could not have been sent to hospitals for the insane, if it had not been for the relations which were established with the relatives while the patients were at the hospital on the neurological service. So, though this service was not established as a psychiatric clinic, and is not primarily a psychiatric clinic, to this day it has justified its existence by the service it has been able to give in this class of cases alone.

DR. E. S. ABBOT: I am glad Dr. Knapp emphasized so strongly the fact that it is necessary for the physician in charge of these mental cases to know how to treat them. Neither the general physician nor the house officers do know. During my four years' service in an executive capacity at the Boston City Hospital I saw several cases literally done to death by bromides and other sedatives. When I tried to remonstrate, I was looked on as not really knowing what I was talking about. I do not see how the general practitioner can know any better. Almost all the text-books on general medicine recommend or at least suggest sedatives in case mental symptoms of any sort arise. The medical student is taught that way, and so he practices.

In the delirious cases, especially delirium tremens, the patient has been taking poor care of himself; he has been eating too little, and though he has been drinking, his water intake has not been sufficient, and he has usually neglected his bowels. He is suffering, therefore, from semi-starvation, lack of food and water, he has a toxemia, and his gastro-intestinal tract is irritated. What does he need? Abundant water, simple abundant food, flushing out of the bowels. He does not need an additional toxin—bromides, etc.,—which he must eliminate. The deliria of acute infectious diseases are similar, probably due to the exhaustion and the toxemia from bacterial poisons. It seems to me quite irrational to add a toxin to the body already suffering from toxemia, merely for the relief of one symptom, and that not a fundamental or important one.

A word as to the amount of food and water needed. Most of these cases get far too little. We need to make sure that they get a sufficient

number of calories. Some years ago I looked up the food values of the diet we were giving at McLean to tube-fed patients. I was rather surprised at the difference on different wards. The calories varied from 2900 to over 4000 a day. The amount of liquid was pretty uniform,—72 oz. a day. The average stomach can hold without regurgitating about 24 oz., so we put the requisite number of calories into three daily feedings of that amount. I think the 72 oz. of liquid is about the minimum that patients can get along on. The need of water was well illustrated by a case we had some twenty years ago. He was confused and was rapidly exhausting,—he might have been considered a case of Bell's mania in the older days,—but his color was high, and an examination of the blood showed over 6,000,000 reds and 115% of hemoglobin. That meant that he was drying up, desiccating. His improvement was remarkably rapid when he was given enemas of water to retain, and was fed by tube, with consequent reduction in red cell count and hemoglobin. We are apt to overlook the water intake in the confused or delirious patient, but it is highly important.

DR. A. W. STEARNS: I have had the good fortune to have worked under Dr. Knapp at the Boston City Hospital and more recently have been at the Psychopathic Hospital, and I can say that the ideals for which he has been striving are identical with those which have, I think, been realized at the Psychopathic Hospital.

DR. E. S. BOLAND: The Boston City Hospital is fortunate in having the services of such men as Drs. Knapp and Thomas to care for these cases which are sure to turn up in the wards and outpatient department of every large hospital. The results are brilliant in spite of the lack of a special ward and trained nursing. For the visiting staff, internes, and nurses such acute mental cases have an invaluable educational importance, but their presence in the common wards is a sore trial to other patients. For the ordinary sick, injured, or post-operative case the ordinary ward is not a bed of roses, and if they are to have the added infliction of a jimjam or epileptic in adjoining beds, they too might want to "take to the woods." Therefore, unless the City Hospital can devote a separate ward to the service, I protest against the reception and care of such patients in the wards.

DR. KNAPP in closing, said he may have had luck in dealing with the executive department of the hospital, but he regretted that Dr. McCollum was unable to be present and tell how much the executive department had suffered in at least half of the last four years from his complaints and persistence in keeping patients before committing them. He had not meant to be understood that a hydrotherapeutic plant and a suitable psychiatric ward were undesirable,—they were, of course, a very great help,—but the idea of having mental cases in the hospital was really contrary to the rules, and it had not been thought best to call attention too strongly to the subject, by urging a special ward. Without these advantages he had managed to get along without much trouble. As to keeping patients who were actually insane in the hospital, instead of sending them to a hospital for the insane he had been guided by circumstances. If a patient seemed to be improving rather rapidly, despite the disadvantages of the hospital, he kept him. If a patient had to be tube fed or if he were very violent, as in epileptic mania, he was naturally committed in a few days. It was obviously a bad thing for a sane patient to be in the ward with noisy and delirious cases, and a ward with better facilities for isolation was most desirable. He agreed fully with Drs. Abbott and Tuttle that these cases had been often badly treated in years past. Not only had there been excessive use of restraint and of drugs, but there had also been a superstition that the alcoholic patient must have alcohol to prevent the development of delirium tremens. Time and again had he seen alcoholic patients in the wards in the medical and surgical services—oftener in the medical than in the surgical,—where he had in vain urged cutting off alcohol absolutely, feeding the patient as much as possible, and flushing him out thoroughly. The alcohol would be kept up,—and the patient died.

Book Reviews.

Structure and Inflammation of the Heart Valve Tissue. By PROFESSOR DR. PAUL GRAWITZ, With five photographic tables. Berlin: Richard Schoetz. 1914.

In this monograph, from the institute of pathologic anatomy at the University of Greifswald, the author believes he has demonstrated, by cell cultures *in vitro*, that the small round cells of inflammatory tissue are not wandering hematogenous elements, but are derived from the cells of the inflamed tissue. In endocarditis there is no invasion of new cells, but a defensive cell metamorphosis analogous to that seen in the normal development of heart valve tissue. The work is admirably illustrated by twelve photomicrographic figures.

The Intervertebral Foramen. By HAROLD SWANBERG. Chicago: Scientific Publishing Company. 1914.

This monograph, described in its sub-title as "an atlas and histologic description of an intervertebral foramen and its adjacent parts," consists of a series of 16 admirable full page plates, with descriptive text, illustrating a study of the first thoracic intervertebral foramen of a cat. It is not, however, primarily, a study in anatomy or in comparative anatomy. Indeed, the purpose of the work is best indicated in the introductory note by Dr. Harris E. Santee: "Mr. Swanberg," he says, "shows by actual sections the exact relations of the first dorsal nerve at the intervertebral foramen. A study of his work will help to determine whether compression of the nerves at this point is likely to occur; and whether, therefore, there is substantial ground for the doctrine that such compression is the immediate cause of all or of a considerable number of pathologic conditions." Apparently the author believes that such compression is unlikely, or at all events very infrequent.

Diseases of the Rectum and Pelvic Colon. By MARTIN L. BODKIN, M.D., New York, rectal surgeon, St. Mary's Hospital, the Williamsburgh Hospital and the Howard Orphan Asylum; late rectal surgeon, Bushwick Hospital. Illustrations specially drawn by Francis A. Deck. New York: E. B. Treat and Company, 241-3 West 23d Street. 1913.

An admirable small handbook of four hundred pages with about one hundred illustrations which are, without exception, very good and a distinct help to the reader. The writer has endeavored to master "the relationship of proctology to the many ailments generally treated by the regular practitioner" and presents his views in the plainest and most direct language. An examination of the book shows that he has well attained this purpose. Only modern operative technic is outlined.

The book is a safe and interesting guide to the treatment of rectal and colonic diseases.

Clinical Surgical Diagnosis. For Students and Practitioners. By F. DE QUERVAIN, professor of surgery and director of the surgical clinic at the University of Basle. With 510 illustrations and 4 plates. Translated from the fourth edition by J. SNOWMAN, M.D. New York: William Wood and Company. 1913.

The author's name is well known to all who follow the progress of surgery of the foreign clinics. He is a man of wide experience and his work is characterized by accuracy of observation and of technic, and by excellent results. In the preface of his book he tells us that it is the outcome of years of association with students as a teacher, and with medical practitioners at consultations. It is concerned entirely with diagnosis, which includes not only the most recent diagnostic methods, but also some of the best of the earlier methods which are sometimes in danger of being forgotten today. Throughout, the book begins with symptoms and progresses towards conclusions and cites a very large number of actual cases; histories are produced in a few lines. He is enthusiastic about differential diagnosis, but says, "Diagnosis is not to be made for its own sake, but as a means to cure," and warns against loss of time while refinements of diagnosis are being investigated. Illustrations, with rare exception, are his own. They are very numerous and admirable, whether they appear as half tones, as diagrams, as x-ray plates, or as colored full-page illustrations. Indeed, the volume is the most entirely satisfactorily illustrated book which we have seen in months. The arrangement is on the anatomical basis.

The book is divided into six parts:—

1. Surgical Diseases of the Head.
2. Surgical Diseases of the Neck.
3. Surgical Diseases of the Thorax.
4. Surgical Diseases of the Abdominal and Pelvic Viscera.
5. Surgical Diseases of the Pelvis and Spinal Column.
6. Surgical Diseases of the Extremities.

Throughout the book, characteristics of accuracy in observation, condensation of symptoms, and logical reasoning, are everywhere in evidence. We have not yet discovered a condition of any importance which has been omitted, nor one which is considered to unnecessary length.

Indeed, the book seems to be entirely without obvious fault or omissions and may cordially be recommended as a most admirable and interesting text-book on surgical diagnosis.

Diagnostic Methods. By HERBERT THOMAS BROOKS, A.B., M.D. Second edition. Revised and rewrittten. St. Louis: C. V. Mosby Company. 1914.

This volume is sufficiently described by its sub-title as "a guide for history taking, making of routine physical examinations and the usual laboratory tests necessary for students in clinical pathology, hospital internes and practicing physicians." In this second edition, a chapter has been added on Schwarz's complement fixation test for gonorrhea.

A Manual of Operative Surgery. With Surgical Anatomy and Surface Markings. By DUNCAN C. L. FITZWILLIAMS, M.D., Ch.M., F.R.C.S., Eng.; F.R.C.S., Edin., surgeon in charge of out-patients, St. Mary's Hospital; senior assistant surgeon to Paddington Green Children's Hospital; lecturer on clinical surgery and joint lecturer on operative surgery, St. Mary's Hospital Medical School. New York: William Wood and Company. 1913.

A small book of four hundred and fifty pages "written for the instruction of the apprentice and to help the journeyman craftsman of our profession." The elementary teaching is derived from that received both at Edinburgh and London, crystallized by a long experience of coaching for the higher examinations. It is not easy to say just what ends this volume is intended to meet. It is a little larger than Treves' hand-book and very much smaller than Treves' Operative Surgery, or the Operative Surgery of Beckham. It is illustrated with a large number of wood-cuts, on the whole very good. It is at least half concerned with the more or less old fashioned method of operations on arteries and on bones. These are given at times in

somewhat unnecessary detail, while farther on the complicated operative technic of stomach and intestines is dismissed rather briefly. It is, no doubt, a good hand-book for students, but is not, in the reviewer's judgment, in any way superior to two or three hand-books already in existence, notably that of Treves, to which reference has already been made. For this reason, it cannot be enthusiastically recommended.

Gunshot Injuries. How They are Inflicted. Their Complications and Treatment. By COLONEL LOUIS A. LAGARDE, United States Army Medical Corps (Retired); late commandant and professor of military surgery, United States Army Medical School; professor of military surgery, medical department, N. Y. University, etc. Prepared under the direction of the Surgeon-General United States Army and published by authority of the Secretary of War. New York: William Wood and Company. 1914.

Dr. Lagarde's book, a volume of convenient size, and of four hundred pages, must be accepted as the present authority upon gunshot wounds. We will say at the beginning that it is well bound and clearly printed and illustrated by a large number of pictures and diagrams, almost all of which are entirely new and which are distinctly good both as technical reproductions, and as supplements to the text. In his preface, Dr. Lagarde says that as far as possible, "I have presented the characteristic feature of wounds by the old armament in preantiseptic times, and compared these with the results of gunshot injuries by modern arms in the Spanish-American, Anglo-Boer, Russo-Japanese and Turko-Balkan Wars, and have also availed myself of the character of wounds by firearms in civil life, and their results as compared to similar wounds in the military service. Like observations have also been made to a less extent on wounds by different kinds of rifles, pistols and revolvers on animals, experimentally and in the hunt." He also includes a chapter on medico-legal phases of gunshot wounds; lectures in civil and military medical schools form the basis of the book. Chapters have been revised in the office of the chief of ordnance, and surgeon-general; the volume may, therefore, be accepted as official from the viewpoint of the medical department of the United States. There are fourteen chapters beginning with definitions, followed with characteristic symptoms and treatment of wounds in general, and then a half dozen chapters of special wounds,—head, chest, abdomen, etc. An index completes the volume.

It is somewhat disconcerting to discover in reading the chapter on gunshot wounds of the abdomen, that the latest authority seems a trifle in doubt as to the advisabiilty of immediate operation on abdominal gunshot wounds, even in civil life; most of us have considered that indication was absolute even though the wound was more than twenty-four hours old, and it is surprising to find that so high an authority as Dr. Lagarde seems to have some doubt in the matter. There can certainly be no possible doubt that the earlier the operation, the better the patient's chances. The volume may cordially be recommended to every surgeon interested in this important surgical subject.

The Surgical Clinics of John B. Murphy, M.D. October and December, 1913.

The October number of these always interesting surgical magazines contains, besides a well illustrated article on hernia, Dr. Murphy's views upon appendicitis, including, of course, his sequence of symptoms and his differential diagnosis. There is also a talk on cancer by Dr. W. L. Rodman, of Philadelphia; an article on joint affections, Hirschsprung's Disease, besides a series of interesting individual cases.

The December number has a very interesting article on Dr. Murphy's method of producing artificial pneumothorax by injection of nitrogen, with a brief historical survey of the subject. Also, two students' clinics given at the opening of the school year illustrating Dr. Murphy's method of instruction; an article upon cholelithiasis and pyonephrosis; a number of bone cases and a list of cases operated on and demonstrated by Dr. Murphy during the week of the Clinical Congress of Surgeons, Nov. 10 to 15, 1913, in Chicago. This formidable list includes one hundred and forty-nine individual cases, covering apparently almost the entire field of surgery, showing an unusually large number of bone cases.

The Clinics continue to be invariably suggestive, whether one agrees with Dr. Murphy's views or not.

Pyorrhea Alveolaris. By FRIEDRICH HECKER, B.Sc., D.D.S., A.M., M.D. Illustrated. St. Louis: C. V. Mosby Company. 1913.

The purpose of this book is to expound its author's theory of *pyorrhea alveolaris*. He believes it to be a general infection, which may be due to various bacterial organisms, with local manifestation in the alveolar process, gum, and peridental membrane. He classifies eleven different varieties of pyorrhea and describes nine species of bacteria which may be its cause. The essence of his treatment is bacteriologic determination of the cause, followed by the preparation and administration of a suitable autogenous vaccine. Whatever the ultimate value of his theory, its exposition constitutes a useful contribution to the literature of the subject.

THE BOSTON

Medical and Surgical Journal

THURSDAY, APRIL 23, 1914.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States. $6.56 per year for all foreign countries belonging to the Postal Union.*

Papers for publication, and all other communications for the Editorial Department, should be sent to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston. All orders for reprints must be sent in writing to the Editor on or before the day of publication.

The Journal will furnish 100 reprints free, if requested in writing.

All letters containing business communications, or referring to the publication, subscription or advertising department of the Journal, should be addressed to the undersigned.

Remittances should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 Tremont Street, Boston, Mass.

MEDICAL INSPECTION OF IMMIGRANTS.

Owing to the recent agitation concerning immigration, the timely subject in this number will bear careful reading. A review of the Immigration Service annual reports show that the most important function of the immigration inspection lies in the medical examination. If an alien is sound in body and mind he is not likely to do much harm. A careful appraisal of our human imports then is a serious matter and one to require thought. Doubtless more aliens are held and appeals taken for medical reasons, directly or indirectly, than any other.

Dr. Nute has had a broad experience in immigration work and a chance to see all sides, having been stationed on the Canadian border, Ellis Island, N. Y., and at the port of Boston. He shows that from the earliest times undesirables have been attracted to this country; that as communities grew restriction followed just as naturally against the alien human being as the alien goods in the market of trade. Among the early adventurers were persons sent to America to serve out penal offences, to escape prosecution, and persons suffering from the Wanderlust. Among the latter were many types that undoubtedly today would be recognized as mental defectives. Later on those who had acquired settlement, having defective relatives, were naturally anxious to have the defective relative at hand, more particularly so when American institutions gained the reputation of dealing more kindly with the inmates than the home asylums.

It is important to understand that it is only since 1903 that financial penalty has been placed upon the steamship companies in addition to returning the alien to the port of embarkation of his home town. Also that there is always the appeal, hence the chance of a good gamble, as the ship has to return to Europe in the natural course of events. It is only since 1907 that the feeble-minded have been mandatorily restricted. Microscopical evidence must be present to certify certain conditions, as tuberculosis, gonorrhea, favus, ringworm, etc. Any physician thus can understand how many incipient tuberculous persons may be admitted. Tuberculosis in the meaning of the law refers only to the lungs, genito-urinary, and intestinal tracts. Persons suffering from tuberculosis of the bones, joints, skin, glands, etc., may be landed. In fact, persons with pulmonary tuberculosis can be landed according to certain departmental decisions.

The immigration law, like most other laws, has for nearly every rule an exception, and the alien with money and influence may utilize it to his advantage. The doctor never admits an alien, neither does he ever exclude one; that is the function of the immigration officials.

Those who have travelled can readily realize the difficulties of cabin inspection, which often has to be made after dark, with poor light, and even in daylight in cold and stormy weather some place has to be sought that may not delay the ship or passengers. To do this without delaying traffic, without putting passengers to inconvenience, passengers that often are nervous, tired and irritable after a long journey, who resent being asked personal questions, certainly requires tact.

Observation has taught these examiners a great deal both in a knowledge of human nature and the practical recognition of diseased conditions. To the visitor the spectacular line work seems to be about all there is, but he rarely follows behind the scenes and learns what happens to those who turned into the detention rooms. The hardest work is often between ships, when cases have to be carefully recorded, after due examination that carries with it the hard work of any hospital examining rooms. The mental examination may readily be seen to be a different matter than any institution has to face. Here the examiner must pick out the defectives from the mixed stream flowing past. After picking out a suspect, the doctor receives no aid

from the alien's relatives or friends. Instead, all sorts of pressure will be brought to bear to discredit the examiner.

During the past year the work at Boston has markedly increased. New lines have entered, but the type of immigrant has changed. Not many years ago most of Boston's immigrants came from Northern Europe and the British Isles. Today southern and eastern Europeans predominate and emigration is beginning from Turkey in Asia and Persia.

Boston is sadly in need of a proper immigrant station, both for protection of the public and in fairness to the detained immigrant. The present quarters are inadequate in every way. It does not require much of a rush of traffic to fill it to overflowing and cause many to be detained on ship board until such time as room can be made by either landing or deporting those detained on Long Wharf. It should be kept in mind that detained aliens are not felons, but human beings waiting to prove their right to land, or waiting the sailing of the ship to return them to their homes. Boston is fortunate in having a well trained medical staff, but the best carpenter cannot build much of a house with a jack knife, and it is only due to the vigilance of these doctors that serious outbreaks of diseases have not occurred.

As a result of much injudicious talk on the part of some of the newspapers and magazines, there has been built a false situation, either by those that do not understand or those that are prejudiced against restriction.

If every charitable institution, prison, or hospital supported in any part by public funds, would report to the Immigration Service or in an annual report every inmate who is a public charge or who is seeking free aid, the taxpayers might learn something not hitherto realized.

There is only one reason for restricting immigration, and that is the protection of American institutions. There are many reasons for laxity, such as cheap labor, foreign commercial companies' traffic products, and a cheap vote easily controlled.

The feeble-minded problem is one of the most serious, for it is more open to dispute, and less likely than the insane to become a public charge. Many forms of insanity are curable, and at least usually recognizable; but the feeble-minded are the more dangerous, as they never play the normal in life's competition and often go for years or life unrecognized.

The best remedy is honest enforcement of the law,—make every public office holder seeking to land a defective alien enter his name as a sponsor in the public records, more authority and better facilities for the medical department, a better division of work so that efficiency may not be diminished by speed, even if more medical officers are required, and lastly a clearer understanding on the part of the public that has to pay the bill.

Every alien should be required to show the United States that he is clearly and beyond a doubt entitled to land in this country, instead of requiring the United States constantly to be on the defensive.

IMPORTANT MEETINGS IN NEW YORK.

SEVERAL important surgical and medical meetings have been held in New York during the past fortnight.

The annual meeting of the American Surgical Association was held in New York on April 9, 10, and 11. At the sessions on the first day addresses were made by Dr. William J. Mayo, of Rochester, Minn.; Dr. James E. Moore, of Minneapolis, Minn.; Dr. A. G. Gerster, of New York; and Dr. George W. Crile, of Cleveland, Ohio. On April 10, Dr. Alexis Carrel, of the Rockefeller Institute for Medical Research, reported a series of experimental operations on dogs, in which the great vessels at the base of the heart were clamped and the heart action stopped for two or three minutes to enable surgical procedures on the cardiac valves. In a series of 12 dogs, thus treated only 2 died, the remainder being perfectly well at the end of four months.

Other speakers were Professor Robert Proust of Paris, Dr. George E. Armstrong of Montreal, Dr. Fred T. Murphy of St. Louis, Dr. Howard Lilienthal of New York, Dr. James G. Mumford and Dr. Samuel Robinson of Clifton Springs, N. Y., Dr. Willy Meyer of New York, Dr. James E. Thompson of Galveston, Dr. Joseph Ransohoff of Cincinnati, O., Dr. A. J. K. MacKenzie of Portland, Ore., Dr. Charles H. Mayo and Dr. E. H. Beckman of Rochester, Minn., and Dr. John P. Murphy of Chicago.

The annual meetings of several other societies were held at the New York Academy of Medicine at the same time as that of the American Surgical Association. On April 9, the

Society of Sanitary and Moral Prophylaxis discussed the control of medical charlatans. At the meeting of the pediatric section, Dr. John Lovett Morse, of Boston, discussed the clinical and sociologic aspects of pertussis. In the evening of April 10 the American Society for the Control of Cancer held a public meeting, at which Dr. William J. Mayo made the opening address. Dr. J. Collins Warren, of Boston, reported the work of the Harvard Cancer Commission.

At the closing session of the American Surgical Association on April 11, papers were read by Dr. Richard Sparmann of Vienna, Dr. Robert Abbe of New York, Dr. Kenneth A. J. MacKenzie, and Dr. J. M. T. Finney, of Baltimore. Rochester, Minn., was selected as the next place of meeting, and the following officers were elected for the ensuing year:—

President, Dr. George E. Armstrong, Montreal; vice-presidents, Dr. Lewis S. Pitcher, Brooklyn, and Dr. Frank E. Bunts, Cleveland; secretary, Dr. Robert G. Le Conte, Philadelphia; treasurer, Dr. Charles L. Gibson, New York.

On April 13 the fourth triennial convention of the International Surgical Association was opened in New York at Hotel Astor. There were addresses by Surg.-Gen. Gorgas of the United States Army; Dr. W. J. Mayo; Prof. Charles Williams, chairman of the international committee; Prof. A. DePage president of the congress; and Dr. Lewis L. McArthur, chairman of the American committee.

The afternoon session was devoted to the reading and discussion of papers on amputation. Papers were read by Dr. Witzel of Düsseldorf, Dr. Geci of Pisa, Dr. Durand of Lyons, Dr. Razzi of Vienna and Dr. Binnie of Kansas City.

The subjects discussed at the remaining sessions of the convention were:—

1—"Gastric and Duodenal Ulcers," by De Quervain of Basel, Hartman of Paris, Mayo of Rochester, Minn., Moynihan of Leeds, and Payn of Königsberg.

2—"Grafts and Transplantations," by Morestin of Paris, Villard of Lyons, Ulmann of Vienna, Lexer of Jena, and Alexis Carrel of New York.

At the concluding session on April 15, it was voted that the fifth convention be held at Paris in September, 1917. The Association was organized and held its first meeting at Bruxelles in 1905, and the conventions of 1908 and 1911 were also held in that city.

During the week following the convention in New York, many members of the Association have made excursions to Baltimore, Boston, Buffalo, Chicago, Philadelphia, Rochester, Minn., and Washington.

AMERICAN POSTURE LEAGUE.

Official announcement was made on April 2, of the incorporation at Albany of the American Posture League, a national body formed to improve human health and efficiency, through interesting the public in correct physical posture and the improvement of conditions affecting it.

The new organization is concerned with the sitting and standing position of children in schools and of adults in shops, offices, factories and elsewhere. It hopes to effect a more general use of scientific and healthful principles in seating accommodations for working purposes and for public audience rooms and vehicles.

"Correct standing posture is defined briefly as one in which the different segments of the body,—head and neck, chest, and abdomen,—are balanced vertically one upon the other, so that the weight is borne mainly by the bony framework, and a minimum of strain or effort is required of the muscles and ligaments. In this posture, under normal conditions, the organic functions,—respiration, circulation, digestion, etc.,—are performed with least mechanical obstruction and with the greatest efficiency.

"Many conditions of school, factory, personal and public environment exert a molding influence upon the posture of the body. Those conditions inhere largely in furniture and clothing, in habit posture, changes in position and occupation, rest conditions and related matters.

"Good chest development cannot be expected of a boy when the shape of his school seat and the cut of his coat force him for many hours each day into faulty postures. Thousands of children who carry heavy loads of school books are forced into distortions of posture that in all but the most robust must have a serious effect on health and development. Round shoulders are to be expected in a child whose clothing is supported without proper regard for the anatomy and mechanics of the shoulder."

No organized attempt to standardize these various conditions has hitherto been made. Individual orthopedic surgeons, and in a few instances special commissions, have attempted improvements, but the skill and judgment of

the parts have never been combined in united effort. A great field of hygiene and preventive medicine is ready for cultivation, and the American Posture League seems peculiarly fitted to enter it, since it includes in its membershp leading orthopedic surgeons, physical trainers and educators who have specialized on these subjects for years.

"The educational work of the League will be conducted largely by means of illustrated bulletins which it will issue at intervals, each covering some particular phase of the subject. Thus, industrial conditions will be treated in bulletins that will take up the standing occupations, with information on correct standing; how to rest while standing in postures not harmful; foot gear, and habit postures of the feet for such occupations. Similar matters will be treated for the sitting occupations. In several industrial lines the coöperation of the League has already been enlisted, notably for shop girls and motormen. School conditions will have a special series of bulletins, for which much practical, helpful material has been gathered. For general, personal hygiene, bulletins will be issued for physical educators, physicians and others interested. The League hopes eventually to place in the hands of such workers information as to articles, especially in furniture and clothing, that meet scientific standards in regard to posture.

"Lantern slides and lecture outlines for the various conditions mentioned are being prepared, numerous requests for such being on file.

"By all of these means the League will make an earnest effort to popularize strong, rather than weak, standing and sitting postures, and to create an intelligent sentiment in favor of right conditions affecting them."

The League owes its inception to its President, Miss Jessie H. Bancroft, assistant director of physical training in the public schools of New York City. On its board of directors are Dr. Frederick R. Green, of Chicago, secretary of the council on Health and Public Instruction of the American Posture Association; Dr. Joel E. Goldthwait of Boston, ex-president of the American Orthopedic Association; Dr. R. Tait McKenzie, the well known sculptor, who is a director of the physical education department of the University of Pennsylvania; Dr. Henry Ling Taylor, professor of orthopedic surgery in the New York Post-Graduate Medical School; Dr. Thomas A. Storey, professor of hygiene and physical instruction in the College of New York; Dr. S. Josephine Baker, director of the Department of Child Hygiene, New York City Board of Health; Dr. Eliza M. Mosher, of Brooklyn; Dr. Eleonora Everhard, of Dayton, Ohio; Dr. William H. Burnham, of Worcester, Mass., and Dr. E. G. Brackett of Boston.

MEDICAL LEGISLATION. THE BAGSHAW VACCINATION BILL.

In the issue of the JOURNAL for April 2 (p. 559) we published a communication from Dr. George W. Gay on "Antivaccination and the Legislature." In spite of the protest of the Massachusetts Medical Society, which he represented, and of the profession at large, the Bagshaw bill (House No. 1018) to which he referred, was last week passed by the State Senate. As Dr. Gay pointed out, this bill is virtually "an entering wedge for the repeal of all laws relating to vaccination." As it now stands, it provides that "any child or person who has rached the age at which attendance at school is permitted or required, and who is otherwise eligible for enrollment, who presents a written statement, signed by either a parent or guardian, if such child or person be a minor, or by himself if the person has reached the age of twenty-one, which declares that such parent or guardian or person is opposed to vaccination, shall not, as a condition precedent to admission to the public schools, be required to submit to vaccination, and shall be allowed to attend the public schools, except at the time of a threatened or actual outbreak of smallpox, when the school board shall temporarily debar such child or person from the public schools."

Conscientious objection to vaccination has for some years been legally tolerated in Great Britain, with the inevitable result that smallpox, though still infrequent, is far more widely prevalent in that country than, for instance, in Germany, where compulsory vaccination is enforced. In another column of this issue of the JOURNAL we print a description of two recent epidemics of smallpox in communities not universally protected by vaccination. Such epidemics will infallibly occur in Massachusetts if any appreciable number of children or other persons are allowed to remain unvaccinated. To be sure, only the unvaccinated will be infected and die; but the expense, loss, and industrial and eco-

nomic disturbance must be shared and borne by all.

The Bagshaw bill has not yet been passed by the House, so that there is still a possibility that it may not become law. That it may not do so, is the earnest desire of all physicians and other sensible persons in the community.

MEDICAL NOTES.

Bubonic Plague in Havana.—In recent issues of the Journal we have recorded the occurrence of several cases of bubonic plague at Havana. Two new cases of this disease were discovered in that city on April 11 and another on April 12, making a total of 5 then under care in hospital. Three blocks of houses in the infected district were closed, and the residents ordered to vacate by the sanitary department. By order of Dr. Juan Guiteras, director of sanitation, 12 blocks in the commercial district were also closed for thorough deratization. Report from Havana on April 14 states that two more cases of bubonic plague have been discovered in the city, making a total of 7.

A Declining Welsh Death-Rate.—Statistics recently published indicate that in the ancient town of Pwllheli in Wales the total mortality has steadily declined for the past 35 years. In the decade ending in 1888, the death-rate was 21.7 per 1000 inhabitants; in that ending in 1904 it was 18.8; in the period 1905-12 it was 17.05; and in 1912 it was only 9.45.

Walsh Radium Bill.—Among the measures now pending before the national senate is the Walsh radium bill, which aims to safeguard the radium bearing lands of this country from private exploitation. In its amended form it provides for "a prior right of purchase by the Government on all radium ores taken from lands located after the passage of the act. It also provides for a Government owned and operated plant for the reduction of radium ores and the manufacture of the various radium salts employed therapeutically. The Bureau of Mines already has perfected a process of extraction and is prepared to begin radium making immediately."

If government control of radium production be desirable, the national legislature has already lost much valuable time in establishing it, since many claims are being occupied, over which the United States can never exercise the jurisdiction given it by the bill.

A Prolific Centenarian.—Mrs. Pauline Porrell, of Sanford, Me., who died on April 12, is said to have been born in September, 1813. She is survived by eight children, 49 grandchildren, and over 80 great-grandchildren.

BOSTON AND NEW ENGLAND.

Typhus Fever at Providence.—Report from Providence, R. I., states that on April 15, 3 cases of typhus fever were discovered among Greek immigrants aboard the steamer *Madonna* recently arrived from Mediterranean ports. The patients were taken to New York for detention.

Mount Sinai Hospital, Boston.—The recently published twelfth annual report of the Mount Sinai Hospital, Boston, records the work and progress of that institution for the calendar year 1913. During this period 24,324 treatments were given in the various departments, and 339 obstetric patients were attended in their home. All the departments are much handicapped in their activities by lack of room. The dental department has been closed. The plan for a Jewish Hospital has been postponed until after a new dispensary building has been erected.

Massachusetts School for Feeble-Minded.—The recently published sixty-ninth annual report of the trustees of the Massachusetts School for the Feeble-Minded at Waltham, records the work and progress of that institution for the year ended Nov. 30, 1913. At the close of that period there were 1335 inmates of the school at Waverley and 292 in the farm colony at Templeton. The report contains an admirable statement of the classification and method of training and instruction. The principal present needs of the institution are two new cottages, a visitors' and recreation building, a steel water tower, and a cottage for 15 additional patients at Templeton.

New Contagious Building at Boston City Hospital.—It is announced that work is soon to begin on the new contagious disease building

of the Boston City Hospital, for which an appropriation of $297,000 was made last summer. The site is on Massachusetts Avenue, opposite the main hospital, purchased by the city in 1910. The new building, which is to relieve the present overcrowded condition of the South Department, will accommodate 200 patients, each in a separate room or cubicle, many of the partitions being of glass. This idea of construction was originally adapted from the contagious hospital at Walthamstow, England.

According to the plans, the new building will be of six stories, of which the main floor, that above the high basement, shall be arranged as an isolation ward, with a room for each patient, and all rooms opening on the open-air outside veranda or gallery, which will be used for the open-air treatment of patients. The four floors above will be used for patients convalescent from scarlet fever. The detention ward will accommodate fifty patients, but the entire building will have a normal capacity of two hundred.

OPENING OF THE CHILDREN'S HOSPITAL.—The new buildings of the Children's Hospital, Boston, were officially opened on April 15, with addresses by President Lowell, Dean Bradford, and Mayor Curley. About 2000 invited guests were present. A full description of the new buildings was published in the issue of the JOURNAL for April 2.

CASES OF INFECTIOUS DISEASES reported to the Boston Board of Health for the week ending April 14, 1914: Diphtheria, 34; scarlatina, 112, of which 20 were non-residents; typhoid fever, 5, of which 1 was non-resident; measles, 93, of which 2 were non-residents; tuberculosis, 62, of which 1 was non-resident.

The death-rate of the reported deaths for the week was 17.78.

NEW YORK.

STATE HOSPITAL FOR CRIPPLED AND DEFORMED.—The recently published thirteenth annual report of the New York State Hospital for the Care of Crippled and Deformed Children, located at West Haverstraw, Rockland County, records the work of that institution for the year ended Sept. 30, 1913. During this period 101 orthopedic patients were treated in the hospital wards, with 2 deaths, and 126 in the out-door department. An industrial school is maintained in conjunction with the hospital, and had an average daily attendance last year of 55 pupils.

ADIRONDACK COTTAGE SANITARIUM.—The recently published twenty-ninth annual report of the Adirondack Cottage Sanitarium at Saranac Lake records the work and progress of that institution for the year ended Oct. 31, 1913. During this period 327 patients were treated, of whom 35 were discharged apparently cured, and only 2 died. The appended ninth medical supplement presents a statistic study of cases. In the treatment, both rest in bed, graded exercises, and artificial pneumothorax have been employed. The principal present needs of the institution are a new laundry, increased bed accommodation, two new small cottages, and sleeping-out porches on several of the older cottages.

MERCANTILE ESTABLISHMENTS MAY HAVE TO BE QUARANTINED.—Two hundred cases of smallpox were discovered in Toledo during the months of December, January and February. Of the entire number of sufferers, but one had been vaccinated, and that one was vaccinated thirty years ago. The story of the Toledo epidemic is the story of hundreds of localized epidemics the world over. An epidemic of equal severity would give to New York City seventy-five hundred cases of smallpox in three months, or thirty thousand cases in a year. Such an epidemic would be a calamity to the people and would be ruinous to the city's trade.

The Department of Health is determined that a smallpox epidemic shall not occur in New York. It has asked the people to protect themselves and, by protecting themselves, to protect their neighbors and to save the city from disaster. Many thousands have responded, but the city is not yet free from danger, and the department is now obliged to issue the following announcement:—

NOTICE TO EMPLOYERS.

Employers of labor are expected to have their employees vaccinated.

Notice is hereby given that in case of smallpox developing in any place of employment, the Department of Health will put such place under quarantine.

MARCH DEATH-RATES.—The weekly reports of the Health Department show that the mortality

sented an annual death-rate of 16.42, as against 15.34 in February, and 16.59 in March, 1913. Among the diseases in which there was an augmented fatality were the following: The weekly average of deaths from measles increased from 13.25 in February to 17.5 in March; the weekly average from whooping-cough, from 4.25 to 5.75; from diphtheria and croup, from 44 to 46; from influenza, from 13 to 22.75; from epidemic cerebrospinal meningitis, from 3.75 to 4.5; from pulmonary tuberculosis, from 191.25 to 209; from acute bronchitis, from 15.24 to 19; from pneumonia, from 160.75 to 197; from broncho-pneumonia, from 115 to 145.5; from apoplexy and softening of the brain, from 25.24 to 28.5; from diarrheal diseases under five years, from 30.75 to 33.25; from appendicitis and typhilitis, from 14.75 to 16.25; and from Bright's disease and acute nephritis, from 123 to 126. Among the diseases in which there was a diminished mortality were the following: The weekly average of deaths from typhoid fever declined from 4.25 to 2.5; from scarlet fever, from 16.25 to 13.5; from organic heart diseases, from 249 to 238; from hernia and intestinal obstruction, from 13.5 to 10.5; and from cirrhosis of the liver, from 20 to 18.25.

Veto of Colgate Bill.—Governor Fielder of New Jersey, yielding to the solicitation of the anti-vivisectionists, on April 13 vetoed the Colgate bill, enabling the Rockefeller Institute to establish a branch near New Brunswick, which was passed by the legislature; and this he did in spite of the fact that among those who appeared in favor of the bill were Dr. Simon Flexner of the institute; Dr. J. T. Lipman, director of the experiment station at New Brunswick; and Dr. D. C. English, editor of the *Journal of the Medical Society of New Jersey*, and that special stress was laid on the benefit which the farmers of the state would derive from the institute's studies of diseases of animals.

Veto of the Blauvelt Bills.—Governor Glynn has vetoed the two Blauvelt bills, one amending the Criminal Code in relation to pleas of insanity, and the other the penal law relative to the responsibility of incompetent persons; both of which had the backing of the State Bar Association and the Society of Medical Jurisprudence. With the vetoes he filed a memorandum, a portion of which is as follows: "The purpose of these two bills is to create a new plea, 'Guilty, but insane,' available for defendants charged with crime, and to enact a new legal definition of the term 'insanity'. . . While both bills indicate a sincere attempt on the part of the persons interested in the subject to substitute something better for existing law, I am constrained to the opinion that the subject is one which will require further investigation and discussion before the existing law is amended."

5. Baar discusses the results of his studies of indicanuria as a diagnostic aid in gastrointestinal diseases. He believes that every lesion, no matter how simple, of the gastrointestinal mucosa is sufficient to allow enough indol absorption to cause indicanuria. In these cases he advocates testing the twenty-four hour urine daily for one month, using colonic lavage meanwhile to be sure that the indican does not form in the lower colon, and testing the gastric juice for achlorhydria to exclude this possible cause of indicanuria. Indicanuria may be transitory (due to a

temporary lesion or insufficiency of secretion), constant (due to permanent lesions or insufficiency), or cyclic (recurrent). Cyclic indicanuria may be the only positive evidence of gastrointestinal lesions requiring surgical interference, *e.g.*, chronic appendicitis, cholecystitis, duodenal or gastric ulcer.

7. *ROSENAU, FROST AND BRYANT. *A Study of the Market Butter of Boston.*

2. The spirochete cultivated from the filtrate of water collected from the shores of Jamaica Pond by Wolbach and Binger is shown to be filterable. Passage through a fine filter yields evidently a pure culture of the organism which they have called spirocheta elusa. They have been able to cultivate the organism in fluid and upon solid media by means of hay infusion, which seems to promote the growth of this organism. The filterability of spirochetae in general suggests the employment of this means to separate this group from other bacteria, which are generally not able to pass through the filter.

3. The same authors have discovered another and more delicate spirocheta, also filterable from stagnant fresh water. This organism is so actively motile that its curved ends give a peculiar appearance, from which its name has been constructed, *i.e.* spirocheta biflexa.

7. Rosenau, Frost and Bryant have examined twenty-five samples of Boston market butter. They find no relation between the price and its properties of physical or bacteriological purity. They find that the number of bacteria diminishes with the age of butter. This reduction was as high as 96% in six weeks. In six of the twenty-five samples B. coli was isolated, in fourteen streptococci and in two tubercle bacilli. As a conclusion, the authors recommend most strongly the pasteurization of cream intended for butter production. [L. H. S.]

1. Rosenow has been able to change cultures of the hemolytic streptococcus into the pneumococcus, Str. viridans and Str. mucosus. Similar changes in reverse order are also reported. Mutations have been demonstrated to be complete in all cultural respects

in many instances. The nature of this variation is so obscure that the author suggests the existence of a premutation stage, because the same strains refuse to yield mutations when placed under apparently identical conditions. The latter seem to be of two varieties—in the first place those which call forth luxuriant growth, and secondly those which are unfavorable to multiplication. The latter appears to force the organism to new and latent energies. He suggests as a graphic classification of this group the fingers of the partially flexed hand. The hemolytic streptococcus is represented by the little finger and the pneumococcus, at the other end by the index finger; the Str. viridans by the middle finger and the streptococcus from rheumatism by the ring finger. The Str. mucosus, having properties of both extremes, is represented by the thumb.

2. Cumming finds a vaccine of rabies, dialyzed against running distilled water, to be more efficient as a prophylactic than others prepared in the ordinary manner. This material will protect against 8 M. L. D. Since it is much stronger, the course of treatment necessary to prevent the disease is much shortened. It has been clearly demonstrated that its use is perfectly safe and that the reaction is inconsiderable.

4. Moore finds that the injection of a single dose of anti-typhoid vaccine in an individual artificially protected three years previously causes a sudden, sharp and prolonged increase of anti-bodies. The curves are very striking, in contrast with those of controls; who were treated in the same manner, but without previous protection. This indicates an immunity, though latent, at least three years after inoculation.

5. Rosenow has isolated from a high percentage of "acute joints" in acute rheumatism three varieties of cocci. These are interchangeable, of low virulence and freely susceptible to phagocytosis. All such organisms he groups under the heading Streptococcus Rheumaticus. The reason for his success in isolation of these organisms depends upon the use of dextrose—ascitic-agar media. Material is mixed with the media while it is still fluid. Then the tubes are "fixed." Growth is found 0.5-1 cm. below the top and 2-3 cm. above the bottom.

8. Breed shows that the cells in milk are polynuclear leucocytes or endothelial cells. The presence of the former is not necessarily due to pus formation, nor the presence of blood in the milk. The leucocytes are extended through the capillaries and are thrown off into the milk much as the lining endothelium of the milk glands is desquamated. Hence the presence of these cells in large numbers is not an indication of milk impurity. The strippings always contain much higher cell counts than does the first part of the milking. There is great variation in cell count in the same cow from day to day and from different quarters of the same udder, as well as from different portions of the same milking.

11. Davis states that the actinomyces-like granules found in the tonsil are in no way related to the ray fungus. They consist chiefly of bacilli, streptococci and spirilla. He even states that there does not appear to be a well authenticated case of primary actinomycosis of the tonsil yet reported.

13. Berry, in line with so many others, has examined the blood of 50 patients suffering from advanced phthisis, for tubercle bacilli. Her efforts have proved fruitless, since she was unable in any instance to demonstrate a simple acid-fast bacillus.

5. *McCarrison, R. *Etiology of Endemic Cretinism. Congenital Goitre and Congenital Parathyroid Disease; Abstract of Experimental Researches.*
6. Morton, R. *The Suppression of Reverse Current in X-ray Coils.*

3. Adamson believes that rodent ulcer is an affection distinct from true malignant carcinoma, and that it belongs to the class of nevoid growths which include andenoma sebaceum and multiple benign cystic epithelioma. His reasons for this belief he describes in detail presenting several illustrative cases.

5. McCarrison presents further evidence for his belief that the exciting agent or agents of goitre exist in the intestinal tract of sufferers. He describes his experiments on rats to demonstrate this theory. He has found that of the offspring of goitrous parents a small percentage are born cretins, 63% are born with congenital goitre, 32% with congenital parathyroid disease, and 33% with normal thyroid and parathyroid glands. Cretinism and congenital goitre are due to the action of toxic substances, derived from the intestines of the goitrous mother, in the fetal thyroid and parathyroid mechanism. [J. B. H.]

6. FLEMING, R. A. *Three Cases of Beriberi.*

2. This is a short practical article on the diet of young children, with special reference to the prevention of dental caries and dyspepsia. The common causes of these two conditions are (1) the lack of breastfeeding and improper feeding, (2) pap(?)-feeding on weaning, (3) sweets, (4) excess of carbohydrate food, (5) lack of animal food. (Exactly what constitutes "pap" the reviewer is unable to discover.) With these points in view the authors lay out a simple schedule for needs.

4. In his first paper Watson made three great classes of conditions due to intestinal intoxication: (1) a neurasthenic group, (2) rheumatoid arthritis, and (3) a "dyspeptic" group. In this paper he proceeds to illustrate the first group of nuerasthenics, citing many cases and showing some admirable x-ray photographs. Next he shows cases to illustrate the relation between intestinal toxemia and arthritis and shows examples of the good results following operation. [J. B. H.]

14. PLAUT, F. *Paul Ehrlich's Sixtieth Birthday.*

1. During the past four years Gennerich has followed over 1200 cases of syphilis. These fall into three groups according to the amount of treatment which they received. In the beginning, Gennerich used salvarsan intramuscularly, later intravenously in small doses. Now he considers that large doses of salvarsan intravenously, combined with mercury, represent the best means of treatment.

Gennerich's results are tabulated. He concludes that fresh lues can be aborted by the proper use of salvarsan and mercury, but that in more chronic cases prolonged treatment is necessary since complete sterilization cannot be so easily obtained.

4. Iwaschenzoff reports on 130 cases of syphilis of the central nervous system which he has treated with intravenous injections of salvarsan or neosalvarsan. He believes that in this form of the disease salvarsan is of great therapeutic benefit and that improvement of symptoms occurs in direct relation to the amount of treatment which has been received. In his experience he has found no difference in the results obtained from using salvarsan or neosalvarsan, but advocates at the beginning of the cure repeated small dosage rather than large, single doses. 6. Schottmüller has already pointed out that the streptococcus viridans is the cause of the majority of cases of subacute infectious endocarditis. Kämmerer and Wegner report a typical example of this disease in which the micrococcus flavus was obtained in blood culture, and was found, morphologically, on the heart valves at autopsy.

Kämmerer and Wegner recognize that this organism is usually an avirulent saprophyte of the mucous membrane of the mouth and throat but believe that it

became pathogenic in their case, superimposed upon an already damaged endocardium. Their observations are reported because in the literature similar findings are almost unknown, and because Kämmerer and Wegner believe that various organisms will be found more frequently in endocarditis if careful bacteriological studies are made in this group of cases.

9. Acute peritonitis in infants and children is a difficult diagnosis to establish on account of its confusing physical signs and lack of typical history. Drachter has found the following manoeuvre useful: The child's thigh is flexed at the hip, the lower leg is held at right angles and the bottom of the foot is struck sharply. The visceral and parietal layers of the peritoneum are brought together by this position, and the blow will often cause definite manifestations of pain if the peritoneal surfaces are inflamed. Drachter does not consider this sign in any way specific for peritonitis. If it is positive, however, in a questionable case, peritonitis is present; if it is negative the other physical signs must determine the correct diagnosis. [R. F.]

Obituary.

ALLAN FOSTER BARNES, M.D.

Dr. Allan Foster Barnes, of Cambridge, Mass., who died in Boston on April 12, was born in Somerville, Mass., on Oct. 6, 1875. He obtained his preparatory education at the Cambridge Latin School, and received from Harvard University the degree of A.B. in 1898 and that of M.D. in 1902. After his graduation, he served for two years as surgical house officer at the Massachusetts General Hospital. He settled in Cambridge, and in 1905 became the city bacteriologist. In 1911 he was appointed to the visiting staff of the Cambridge Hospital.

Dr. Barnes was a Fellow of The Massachusetts Medical Society, a member of the American Medical Association, of the Boston Medical Library, of the Boston Society of Medical Sciences, of the Cambridge Society for Medical Improvement, and a founder of the Aesculapian Club of Boston. He is survived by his parents and two brothers.

In an obituary notice of Dr. Barnes in the daily press, one of his friends writes of him as follows:—

"To his many friends his loss is irreparable. To him loyalty was a religion. He found and gave great happiness when his day's work was done, and he was with those he loved, and his keen sense of humor, as well as his lovable and cheerful personality, created a happy atmosphere.

"His ability to suppress his own feelings in times of stress, personal suffering or disappointment, was remarkable.

"In literature he cared only for the best, and whatever he undertook, he did conscientiously with his utmost ability. To those who knew him his strength of character, loyalty, self-control, courage and great patience were an inspiring lesson and a noble example."

Miscellany.

THE NEW CHILDREN'S HOSPITAL OF PHILADELPHIA.

The Children's Hospital of Philadelphia was established in November, 1855, by private charitable donation. Its present building, erected in 1867, and several times enlarged, has become quite inadequate; and a new hospital of 150 beds is to be built at a cost of $1,000,000, of which over one-third has already been pledged. Plans have been drawn, and the corner-stone of the new structure was laid in October, 1913.

"The buildings will occupy three sides of a square sixty feet in dimension, leaving a great central court, open to the south, to furnish interior light, air and attractive greenery. The main building will be set back from the sidewalk about fifty feet, with projecting pavilions at the ends for operating and service purposes. This will be the administration building. It will face north, and on either side of it will be the wards, turning the corners to the south, while two interior wards will project into the central court. Down the western side will extend the babies' dispensary and out-patient department, and on the opposite side of the court will be the nurses' home.

"The babies' building will have fifty free beds and a training school for nursery maids, while the out-patient building will contain a dispensary with clinics for sick children, a babies' dispensary, a milk laboratory, and means of studying preventive methods through educational work. There is already established a country branch at Wynnefield, about five miles east of the municipal building of Philadelphia.

"The babies' building will contain a check room, where the baby coaches may be left during the visit, and a waiting room. Suspected cases of communicable maladies are to be sent at once to a special detention room in the basement for examination. A partition will separate the waiting babies into two general classes, those requiring medical treatment and those that are well, but whose mothers have been educated to the desirability of bringing the children each week so as to keep them well. Immediately at hand will be a milk room where mothers may obtain at cost either whole or modified milk. There will be various examination rooms for an immediate separation of the nervous, dental patients and the like who have their own waiting rooms. Whooping cough patients will have a special entrance and exit. The best features of modern treatment are to be provided: X-ray room, rooms for surgical or corrective treatment, a gymnasium, etc. A roof garden will be at the service of patients who require fresh air and sunlight and more careful treatment than they are likely to receive at home."

NON-VACCINATION AND VIRULENT SMALLPOX.

THE weekly report of the United States Public Health Service for Feb. 13 states that there has recently been an outbreak of virulent smallpox at Springdale, Washington County, Arkansas. On Feb. 11 there had been six cases, of which four had terminated fatally. The infection was introduced by a person from Tampico, Mexico.

"These cases and the origin of the infection illustrate the manner in which virulent outbreaks of smallpox in this country have started during recent years. For several years a strain of mild smallpox has existed throughout practically all parts of the country. In no instance, however, has this mild infection been authentically shown to have been the cause of a virulent outbreak. All virulent outbreaks in which the source of the infection has been traced have had their origin in some existing virulent outbreak in this country or have been imported.

"The manner in which the strain of mild smallpox existing in this country remains true to type is illustrated by an outbreak which occurred in New Zealand as the result of infection imported from the United States."

A letter from the district health officer at Auckland on Jan. 7 reported this epidemic as follows:—

"We have recently undergone in New Zealand a fairly widespread epidemic of the smallpox of the mild type which seems to have been prevalent in America during the last twelve years. It appeared simultaneously in Australia, where, among nearly 900 cases no deaths have occurred. In our case the disease has been almost entirely confined to the Maori race, who are peculiarly susceptible to infectious diseases, more especially of the pustular type. The cases among these natives were on the whole much more severe than those among Europeans. In some cases the disease had all the appearance of confluent smallpox, and in a small percentage even proved fatal yet other natives infected from such severe cases might take it in the usual mild form, and there was no evidence that it worked up in virulence permanently to the normal degree of severity. The majority of the cases even in natives, very few of whom were vaccinated, were more like chicken pox so far as severity was concerned.

"We were able to trace the introduction into New Zealand to a party of persons who came from Utah by way of Vancouver in the steamer *Zealandia*, landing here on April 8. One of this party had a pustular disease of mild type while on board the steamer. In all, some 2,000 cases occurred, but owing to the fact that the natives are a wandering people without definite places of abode, and do not notify their cases, and rarely send for a European doctor, accurate statistics are impossible to obtain."

These epidemics, like numerous others that have recently occurred in various parts of the country, point the moral of the great risk to any community from the growth within it of any considerable group of non-vaccinated persons.

SOCIETY NOTICES.

SUFFOLK DISTRICT MEDICAL SOCIETY.—The annual meeting will be held at the Boston Medical Library, 8 The Fenway, Saturday, April 25, 1914, at 8.15 p. m.

Paper by Dr. Frederick J. Cotton, "Recent Progress In the Treatment of Fractures." Discussion.

Business: Report of the Librarian, Treasurer, etc. Election of Officers.

Refreshments after the meeting.

HORACE D. ARNOLD, M.D., *President.* WALTER C. HOWE, M.D., *Secretary.*

RECENT DEATHS.

DR. CHARLES HUNT PORTER, formerly of Springfield, died at his home in Taunton, April 16, 1914, aged 42 years. He was a graduate of the College of Physicians and Surgeons of Columbia University and a Fellow of The Massachusetts Medical Society.

DR. CHARLES HENRY BROCKWAY, of Worcester, Mass., who died at the Worcester City Hospital of cerebral hemorrhage April 17, 1914, was born in Boston in 1852. He had been a Fellow of The Massachusetts Medical Society since 1874. He was a graduate of the College of Physicians and Surgeons of Columbia University and previous to settling at Worcester in 1888 had practised in Lynn, Mass., and Avon, Pennsylvania. He is survived by his widow, one daughter and one son.

DR. PAYSON JONATHAN FLAGG, a Fellow of The Massachusetts Medical Society, died at his home in Mittineague (West Springfield), Mass., on March 22, 1914, aged 55. He was a graduate of Jefferson Medical College in 1885.

DR. FRANCIS KELLY ROARKE, who died on April 19 at Troy, N. Y., was born in 1869. He was an otologist and rhino-laryngologist, and was not married.

APPOINTMENTS.

Announcement of New appointments on the reorganized staff of St. Elizabeth's Hospital was made on April 19. The entire staff is now composed as follows.

VISITING STAFF.

Dr. John R. Slattery, superintendent and physician-in-chief. *Dr. Thomas F. Harrington*, associate physician-in-chief. *Dr. M. J. Cronin*, physician. *Dr. John W. Lane*, surgeon-in-chief. *Dr. Edward A. Supple*, surgeon. *Dr. Arthur L. Chute*, chief of urological department. *Dr. Thomas F. Broderick*, orthopedic surgeon. *Dr. Thomas F. Green*, obstetrician. *Dr. P. F. Butler*, roentgenologist. *Dr. Andrew F. Downing*, director of laboratory serum diagnosis. *Dr. Henry S. Rowen*, consulting obstetrician.

OUT-PATIENT STAFF.

Medical Department: *Dr. Thomas J. O'Brien, Dr. Felix McGirr, Dr. Leo T. Miles, Dr. John J. Sullivan.* Assistants: *Dr. Francis J. Doherty, Dr. Joseph Macauley.* Surgical Department: *Dr. Arthur H. Crosbie, Dr. Eugene F. McCarthy, Dr. Joseph Stanton, Dr. George F. Keenan.* Assistant: *Dr. Edward J. O'Brien.* Throat Department: *Dr. John J. Brainard, Dr. Edgar M. Holmes, Dr. John F. O'Brien, Dr. Andrew Sullivan.* Gynecological Department: *Dr. Robert Fair, Dr. Thomas J. Scanlan, Dr. Delbert Jackson, Dr. Charles Kickham.* Eye Department: *Dr. Samuel L. McDonald, Dr. Peter Kelleher, Dr. Peter McAdams, Dr. Jeremiah J. Corbett.* Assistant: *Dr. C. J. Lynch.*

Original Articles.

THE ART OF COMPANIONSHIP IN MENTAL NURSING.*

By Henry R. Stedman, M.D., Brookline, Mass.

Just as the "lunatic asylums" of fifty years ago were built throughout as if violent and physically difficult patients were to be their only inmates, so our training schools of today in hospitals for the insane are almost exclusively devoted to instruction in the treatment and management of acute and violent cases and the physically ill.

It is also an important, but generally unrecognized fact,—and old and experienced nurses bear out these statements,—that in but barely a third of the mental and nervous cases to whom the nurse is called will she† find that the technical instruction which she has had in the training school of the hospital for the insane, is of use to her in private work. By technical duties I mean the management and hygiene of the ward, continuous baths, the care of the physically sick, the preparation and serving of food, and the employment of the various measures necessary for dealing with excited and dangerous patients.

It is only in the acute and other severe cases, which form but a small proportion of the mental patients, that these special requirements are called into play, and then the specially trained, fearless and watchful nurse is indeed a godsend to the patient, the physician and the family. The same remark applies to patients in state hospitals. There, apart from the acute and other excited and difficult cases, are hundreds of quiet, semi-sane or convalescent and generally harmless patients who, even if partially demented, are more or less appreciative, for whom such special and skilled nursing is inappropriate and unnecessary.

Consequently, the nurse soon finds on taking up private work that in most cases she has to fall back upon what native common sense, patience, tact, knowledge of human nature and general information she may possess in order to prove acceptable and helpful to her patients. She finds that if she is ever to be the high-grade nurse of her ambition she will be obliged to be nothing short of a companion to her patient,—who is, for example, one of the many mild melancholiacs or psychasthenics or a case of hypomania living at home,—whom she has to persuade and influence so that she will do the things she ought to do, whom she has constantly to reassure, guide and encourage, and for whom she has to do a number of minor offices never suspected in her course at the training school. In short, she has often to fill the rôle of devoted friend and helper, whether or not her efforts are appreciated and responded to by her charge, and to do such work well is often as difficult and trying a task as to deal with a case of acute mental disturbance, although in a far different way.

It is impossible to specify the many and diverse requirements for skilled personal and individual nursing, for it is nursing and of a high type, although such cases have not to be actually handled, bathed, and dressed or, as a rule, physically controlled. Just as it is not easy to put into words exactly what people in general do that makes them congenial and companionable to their personal friends, so it is impossible to give in detail all the qualities and accomplishments which go to the making of the expert companion-nurse. I will not sermonize on the virtues and accomplishments required of the ideal nurse in this line of work, but simply urge the use of the same means in general that we all employ to win our way with others.

In order, however, to emphasize the wide difference there is between individual and hospital nursing in mental diseases, let us run through a few of the daily duties involved in the private work of the expert mental nurse who is alive to her patients' needs. She reads to her charge systematically and often, so far as possible, selecting desirable books and such as would please her when well. She also sees that the patient reads, even training her to read aloud regularly for a definite time each day. Many a silent, partially demented or melancholic patient has been brightened up and improved by thus exercising the disused function of speech. Reading aloud, especially to single patients in state hospitals is so rare an occurrence that some of us can with difficulty recall an instance of it. Of course, the surroundings and the mental condition and lack of intelligence of many patients make this in a large degree impossible, but a fair number of them are not so demented or so ignorant but that they can be reached by such diversion. Some of them have never learned to read and a few do not know how, but more have never acquired the habit of reading. They can and should be encouraged to learn to like it. The teaching of the more demented is advocated and even practiced in one or two advanced hospitals. Is not then the practice of reading an easy and natural way in which to begin or revive the education of some of the less demented? The libraries of our state hospitals, some of them large ones, do not begin to be utilized for patients as they should be or as they are, for example, at the McLean Hospital. Are the books only for a few intelligent patients in the best ward, who have so many

* Read at a Conference on Modern Developments in Mental Nursing at the Boston Psychopathic Hospital, February 16, 1914, being Psychopathic Hospital contribution 1914.3. Previous contribution by Dr. A. Myerson, 1914.2 entitled "Contralateral Arm Reflexes" was published in the *Journal of Nervous and Mental Disease*, February, 1914.

† For convenience the feminine pronoun is used here in speaking of nurses and patients as the traditional nurse is a woman, but our remarks apply equally to the man nurse and his patient.

other things to interest them? The nurse will also utilize the newspapers, not only for the diversion of her patient, but also for her own improvement, knowing that if she keeps herself informed on the current events of the day or week she will increase her capacity for interesting companionship with all her patients.

It is no news to any intelligent person nowadays that systematic occupation goes a great way toward distracting and engrossing a patient's thoughts. It greatly lightens the companion's task. Most all available kinds are helpful, according to the age, strength and sex of the patients, from embroidery and arts and crafts work to wood cutting and chopping, provided it be free from drudgery and is varied and shared in by the nurse. Dr. Eliot tells us, by the way, that nothing brings content of mind like plenty of hard work that is interesting. The advances made in our state hospitals in this direction have done more than anything else to increase the general content of the patients, the quiet of the wards and a less artificial atmosphere generally.

The nurse will also often have to help in a patient's correspondence and to urge her to write to her relatives or friends. To extort every week or so a few lines of her own composition from a patient may be laborious work, but with patience and persistence not infrequently can be developed into a routine accomplishment when desirable, which will be a help to her and a source of satisfaction to her family. On the other hand, the nurse has also to keep a check on injudicious writing on the part of certain patients, the manic and the paranoid, for example, to accomplish which, without antagonizing them, is anything but easy.

The accomplished companion-nurse will also have as a part of her armamentarium some proficiency at games of various kinds, indoor and outdoor. She will begin early to master solitaire and card games of all kinds and be on the alert for new ones. Out-of-door sports she will pick up with various patients, not a few of whom take a certain satisfaction in teaching the nurse the necessary points.

Regular out-of-door exercise she will make interesting and beneficial by knowing the interesting walks to take and can occasionally cultivate in her charge a love of out-of-door life and nature study. She will also be equally vigilant as to rest hours for her patient as a definite part of the undeviating daily routine of work, play and rest by which the day is hourly piecemealed and which it is so important to establish.

Now personal individual care and attention which is lightly regarded by many as merely "making things pleasant for the patient" and dismissed as "frills" is what, in my experience of thirty years of living in intimate daily and hourly association with mental cases of every description, acute and chronic, mild and violent, makes far more than anything else for the best results that are at all possible. Often the less pronounced acute cases are equally susceptible to their influence. It is the old claim made true of the value of individual care and the nearer we can approach it the better and more scientific is our treatment of the case and the greater the benefit to the patient. In short the methods which really count in the treatment of the mental disease are psychic. Personal attention and influence suitably directed is the essential factor—the *sine qua non*—and to magnify the importance of the technical part of mental nursing is to put the cart before the horse.

We do not for a moment lose sight of the indispensable special methods of treatment for the acute, severe and difficult case of mental disease, continuous baths, the various packs, feeding and close and systematic surveillance which are in constant practice by all physicians in mental cases, but maintain that it is only when the patient's mind has reached a stage when it can be appealed to ever so little by means similar to those I have described that the opportunity for improving her condition begins.

How then is the nurse to fit herself for such important individual duties and acquire the training that is so necessary a part of her life work? She must practice on the patients in the wards. Let her begin by singling out a few for daily regular personal and friendly attention, however slight. It is not enough to be generally kind and helpful superficially to the ward-patients as a whole, as many conscientious and faithful nurses are. She should get down closer to the individual patient. Let her ask her now and then about home and family matters. Our advice to her would be: manage to find time to write a letter home for a patient or two or to help them to do it. Unfailingly encourage good work in whatever the patient does. That costs little time. Acquire and show a little genuine friendly interest and less aloofness toward the individual patient than generally prevails in institutions. All this should not be done fitfully but regularly and systematically, keeping in mind that it is not only the kindly and humane thing to do, but that it is an *important part of your training*, and before long you will not only find a way to extend your influence to others, but will be surprised to see the result to the patient and yourself. Finally when a patient leaves the ward ask yourself whether or not you have made of her a grateful friend and remember that every patient-friend that you have gone out of your way to make, means more to you in future usefulness and practical success in *mental* nursing than months of instruction in hydrotherapy, massage, bandaging, etc., necessary and helpful though they are in special cases.

It follows that all possible means should be tried for giving the nurse who is in training

more time than she now has for such important work directly with the patient. A prominent obstacle, as Dr. Frost has pointed out, is the unnecessary amount of time consumed in study and attendance at the school lectures. There is no question that they could be considerably curtailed without any loss of suitable instruction in the branches that have a direct bearing on nursing in mental disease proper and with distinct gain to the patient. The trouble is that in order to offer a course of training that will attract the right sort of applicants, and heaven knows we need them, certain subjects are taught which relate almost exclusively to physical disease and injury which the mental nurse has to cope with but seldom. In order, therefore, to keep a good staff of nurses for purely mental cases we train them in general nursing in a number of branches that, for practical use, are largely foreign to their legitimate work. An all around training is, of course, desirable for any nurse, but it should not be given at the expense of the patient. The mental nurse would suffer no loss of efficiency and have more time to get closer to her patient if such branches as bacteriology, urinalysis, gynecology, obstetrics and much of the anatomy taught were in some cases omitted altogether and in others materially curtailed. This done, it might be possible to substitute with still a good margin of time, a "current-events" class, for example, a lecture or two on the means for diverting the single patient, reports of personal interviews with patients and their domestic and other troubles which might have a bearing on their condition and their future needs, etc. Prizes offered for the best record in individual work have proved helpful in this direction.

We have enumerated on another occasion the many ways in which a resident social worker in each of our state hospitals could be most useful in the direction mentioned. There is great need of more intelligent lay help other than nurses for hospital patients.

Finally, such methods as are here advocated can only be justly questioned after they have been actually taught and tried in our hospitals. When that is done and they are persistently followed and generally extended, better conditions for recovery will obtain, I believe, the wards will take on a more natural atmosphere and greater ease of administration will follow.

DR. W. W. KEEN HONORED.—At the close of the fourth congress of the International Surgical Association, America was honored by the election of Dr. W. W. Keen of Philadelphia as the president of the next congress. Paris was selected as the place for the meeting of the association in 1917.

CERTAIN ASPECTS OF THE MEDICAL HISTORY OF EXOPHTHALMIC GOITRE.*

BY R. FITZ, M.D., BOSTON.

[From the Medical Clinic of the Peter Bent Brigham Hospital, Boston.]

THE names of three men stand out above all others in connection with the medical history of exophthalmic goitre. These names are Caleb Hillier Parry, Robert James Graves and Carl Adolphus von Basedow. All three of these observers lived within fifty years of one another; all three recognized the symptom-complex which bears their names; all three described the disease from entirely different points of view and for entirely different reasons. It is interesting to compare these various authors and to consider what an important influence, seventy-five years ago, environment and training had on medical observation.

Caleb Hillier Parry was born in 1755. His father was a minister in a small English town, but was so well known a scholar throughout England that Johnson tells us his head teemed with knowledge. Parry was an eldest son. He was sent to a good school and from there went to Edinburgh to learn his profession. From his earliest days he was recognized as having manly sense, calmness of temper and philosophical firmness of mind; his genius, his application, his disposition all promised great things. After receiving his degree, he decided to become a general practitioner of medicine and accordingly moved to Bath in 1779.

At that time Bath was the medical centre of the most fashionable English society. Although Mr. Pickwick visited the city after Parry's death, the times had changed but little and the impressions of that astute gentleman are valuable in showing the kind of patients and the kind of life that Parry had to deal with.

Mr. Pickwick tells us that "a visitor in Bath lead a very pleasant existence with perhaps a slight tinge of sameness. Every morning the regular water drinkers met each other in the pump-room, took their quarter of a pint and walked constitutionally. At the afternoon's promenade all the great people and all the morning water-drinkers met in grand assemblage. After this they walked out, or drove out, or were pushed out in bath chairs and met one another again. After this the gentlemen went to the reading rooms and met divisions of the mass. After this they went home. If it were theatre night perhaps they met at the theatre. If it were assembly night they met at the rooms. The ball nights in Bath were moments snatched from Paradise, rendered be-

* A part of this paper was read at a meeting of The Historical Society of the Harvard Medical School on March 3, 1914.

witching by music, beauty, elegance, fashion, etiquette and above all by the absence of tradespeople. In the ball-room and the passages, the hum of many voices and the sound of many feet were perfectly bewildering. Dresses rustled, feathers waved, lights shone and jewels sparkled. Brilliant eyes, lighted up with pleasurable expectation, gleamed from every side; and look where you would some exquisite form glided gracefully through the throng and was no sooner lost than it was replaced by another as dainty and bewitching."

It was in such gay surroundings that Parry began the practice of medicine. At first it was discouraging. "A great part," he wrote, "of the obstacles to the improvement of the science of medicine originates in the habit of self-indulgence, leading persons to the gratification of present appetite, or the removal of present suffering with little or no consideration of the future. A man shall be grossly ignorant of the whole science of medicine, yet if he has a certain degree of assurance, aided by an adequate number of fashionable phrases, with a determined resolution of flattering his patients by an appearance of great zeal and attachment, and by confirming the good opinion which they entertain of their own discernment in the choice of medicine and diet which they most like, that man shall grow popular and rich and become accessory to the daily destruction of his fellow-creatures."

But as time went on Parry became a fashionable doctor in his turn, and it appears that nearly the whole catalogue of British nobility and many of the most distinguished men in the kingdom came to him for advice. He was even acquainted with the King, who accepted a piece of cloth manufactured from some of Parry's sheep and declared that from its excellent quality, he should feel a pride in wearing it.

In his early days Parry acquired the habit of taking full and complete notes on every case which came under his control. In his later years he contented himself with the more useful task of recording such cases as led to the establishment of principles. His writings therefore are based entirely on his own personal observations and cover a large field of subjects. They were not made, however, from the point of view of a teacher or student of medicine, but rather as objective descriptions of what he saw. This is shown by a quotation of his first case of exophthalmic goitre published in his "Posthumous Papers" in 1825.

"ENLARGEMENT OF THE THYROID GLAND IN CONNECTION WITH ENLARGEMENT OR PALPITATION OF THE HEART.

"CASE 1. There is one malady which I have in five cases seen coincident with what appeared to be enlargement of the heart, and which so far as I know, has not been noticed, in that connection, by medical writers. The malady to which I allude is enlargement of the thyroid gland.

"The first case of this coincidence which I witnessed was that of Grace B., a married woman, aged 34, in the month of August, 1786. Six years before this period she caught cold in lying in, and for a month suffered under a very acute rheumatic fever, subsequently to which, she became subject to more or less palpitation of the heart, very much augmented by bodily exercise, and gradually increasing in force and frequency till my attendance, when it was so vehement that each systole of the heart shook the whole thorax. Her pulse was 156 in a minute, very full and hard, alike in both wrists, irregular as to strength, and intermitting at least once in six beats. She had no cough, tendency to fainting, or blueness of the skin, but twice or thrice had been seized in the night with a sense of constriction and difficulty of breathing, which was attended with a spitting of a small quantity of blood. She described herself also as having frequent and violent stitches of pain about the lower part of the sternum.

"About three months after lying in, while she was suckling her child, a lump about the size of a walnut was perceived on the right side of her neck. This continued to enlarge till the period of my attendance, when it occupied both sides of her neck, so as to have reached an enormous size, projecting forwards before the margin of the lower jaw. The part swelled was the thyroid gland. The carotid arteries on each side were greatly distended; the eyes were protruded from their sockets, and the countenance exhibited an appearance of agitation and distress, especially on any muscular exertion, which I have rarely seen equalled. She suffered no pain in her head, but was frequently affected with giddinesss."

Besides his remarks on this condition, there are found among his medical writings careful studies on thoracic affections, abdominal affections and affections of the genito-urinary organs. His two best known monographs are the "Inquiry into the Symptoms and Causes of Syncope Angina called Angina Pectoris," and "The Nature, Cause and Varieties of the Arterial Pulse." He was interested in many other matters as shown by the titles of a few of his agricultural papers which include, "An Account of a Prize Crop of Cabbages." "Tables of the Female Descendents from 100 Yearling Ewes during Twenty years." "Observations on the English Race Horse."

On the whole, Parry was a fine and elevated character, a man of culture and great charm of manner, a tireless student and note taker. Above all he was a practitioner of medicine, writing, in part, because he had scholarly tastes and scholarly upbringing with such a man's love of the pen, and in part, because, as he said, the business of man was not merely to eat, to drink, to sleep, to enjoy sensual pleasures and then to lay himself down to die, but because it was also the business of man to make the world better after him and to give it the benefit of his experience. He died in 1822.

Robert James Graves was born in Dublin in 1797. He, too, was descended from scholarly people and was brought up in a well-to-do household. His father was a senior fellow of Trinity College and Regius Professor of Divinty, Graves, himself, received a careful preliminary education and went to Trinity College. While there, with two exceptions, he obtained the first prize in classics and science at every examination, and received a gold medal on taking his A. B. degree. He studied medicine with equal zeal and industry, thus it may be assumed that he, too, was a youth of unusual promise.

In Ireland, following its union with England, there was a period of mental inactivity throughout the entire country. Ireland's great men had disappeared, her orators and her advocates were no longer heard unless feebly, and her young men were apathetic. Even Dublin felt the effect of this general mental languor according to Thackeray's description. "A handsomer town with fewer people in it, it is impossible to see on a summer's day. In the whole wide square of Stephen's Green, I think there were not more than two nursery maids to keep company with the statue of George I, who rides horseback in the middle of the garden, the horse having his foot up to trot, as if he wanted to go out of town too. Small troops of dirty children (too poor and dirty to have lodgings at Kingstown) were squatting here and there upon the sunshiney steps, the only clients on the thresholds of the professional gentlemen whose names figure on brass-plates on the doors. A stand of lazy carmen, a policeman or two with clinking boot-heels, a couple of moaning beggars leaning against the rails and calling upon the Lord, and a fellow with a toy and book stall were all the population of the Green.

"At the door of the Kildare Street Club, I saw eight gentlemen looking at two boys playing at leap frog; at the door of the University six lazy porters, in jocky caps, were sunning themselves on a bench,—a sort of blue bottle race— and the Bank on the opposite side did not look as if six pence worth of change had been negotiated there during the day. There was a lad pretending to sell umbrellas under the colonnade, almost the only instance of trade going on."

Since there were few resident nobility or gentry, the professors of law and medicine formed the aristocracy of the city. But the Dublin Medical Schools, too, had suffered from the Irish torpor. Their chief attraction was less the characters of their professors or the number of the original works which issued from them, than the circumstance that of all the cities in the British Empire, Dublin was the one in which the greatest supply of dead bodies for dissection could be obtained. Clinical teaching was unknown, and there was little if any anxiety to encourage the individual pupil to learn.

It was in such surroundings that Graves in 1818 received the degree of Bachelor of Medicine from Trinity College. It must be remembered that he was young, keen-minded, and discerning enough to realize that he had not been educated with any degree of thoroughness. Therefore, as he afterward said, he did not begin life as a practitioner without practice, but for the next three years he studied medicine and the ways of teaching medicine in the better known universities of England, Germany, France and Italy. His trip abroad had a profound effect on his entire life. He returned to Dublin, ardent, energetic, filled with a desire to teach, and well trained not only in clinical subjects, but also, in the allied sciences of pathology, physiology and chemistry. He at once established a private school in medicine and was appointed physician to the Meath Hospital. It was here, that Graves delivered his introductory lecture to the students and pointed out the broad principles of medical education which gave him his unique place in the history of medical teaching.

In this lecture Graves took up the methods of instruction which were in vogue in Italy, France and England. In these countries the clinical side of medicine was taught by a system of ward rounds. The instructor walked from bed to bed examining the patients and expressing his opinions in a loud tone of voice so that the whole audience could hear what was going on. Graves' chief objection to this kind of teaching was that however well inclined the student might be, he was never obliged to exercise his own judgment in distinguishing diseases and had no opportunity to try his skill in their cure.

Graves determined to follow out the German method of clinical instruction. According to this, various members of the class were held responsible for the history, the examination, and the treatment of various cases. At ward rounds each student would report his case in the presence of the instructor, who satisfied himself whether all the necessary particulars had been accurately reported by the pupil. After the patients had been examined the professor and his class proceeded to the lecture room. The pupils were examined concerning the nature of the diseases studied, their probable termination, and the most appropriate method of treatment, each man answering only concerning the patients entrusted to his special care. During the examination the student's diagnosis and proposed remedies were submitted to the consideration of the professor who corrected whatever appeared to be erroneous in either. At the conclusion the prescriptions were read by the professor who strictly commented on, and corrected any inaccuracy or inelegance they might contain. The advan-

tages gained by such "practising pupils" seemed too obvious to require comment; being obliged to give reasons for every plan of cure that they proposed, the students became accustomed to a rational and careful investigation of diseases; and enjoying the most important of all advantages—the early correction of their errors—they commenced private practice with a sufficient degree of experience to render them unlikely to commit any serious mistakes. In other words, Graves believed that the hospital was a place to convert theoretical into practical knowledge; a place to observe the symptoms of diseases previously known to students only through the medium of books or lectures; a place to learn the art of recognizing these symptoms and of appreciating their relative importance and value; a place to study their connection with morbid alterations of internal organs; and, finally, a place to become acquainted with the best method of relieving patients by the application of appropriate remedies. This method of instruction was a radical innovation to the Medical Schools of Dublin, but became entirely successful and gave Graves a universal reputation as a teacher. Trousseau says of him, "For many years I have spoken of Graves in my clinical lectures. I recommend the perusal of his work; I entreat those of my pupils who understand English to consider it as their breviary; I say and repeat, that, of all the practical works published in our time, I am acquainted with none more useful, more intellectual."

As a result of his experience as a teacher Graves published his System of Clinical Medicine in 1843, composed of lectures which had previously appeared in the medical papers of the day. The book contained in it Graves opinion on such subjects as nursing, consumption, the treatment of fevers, etc., and included his remarks on exophthalmic goitre.*

In describing the latter disease, Graves mentions that he had lately seen three cases of violent and long-continued palpitations in females, in each of which the same peculiarity presented itself, viz., enlargement of the thyroid gland. The most typical case is given in detail.

"A lady aged 20, became affected with some symptoms which were supposed to be hysterical. This occurred more than two years ago; her health previously had been good. After she had been in this nervous state about three months, it was observed that her pulse had become singularly rapid. This rapidity existed without any apparent cause, and was constant, the pulse being never under 120, and often much higher. She next complained of weakness on exertion, and began to look pale and thin. Thus she continued for a year, but during this time she manifestly lost ground on the whole, the rapidity of the heart's action having never ceased. It was now observed that the eyes assumed a singular appearance, for the eyeballs were apparently enlarged, so that when she slept or tried to shut her eyes, the lids were incapable of closing. When the eyes were open, the white sclerotic could be seen, to a breadth of several lines, all round the cornea.

"In a few months, the action of the heart continuing with increasing violence, a tumor, of a horse-shoe shape, appeared on the front of the throat, and exactly in the situation of the thyroid gland. This was at first soft, but soon attained a greater hardness, though still elastic. From the time it was first observed, it has increased little, if at all, in size, and is now about thrice the natural bulk of the fully developed gland in a female after the age of puberty. It is somewhat larger on the right side than on the left.

"A circumstance well worthy of notice has been observed in this young lady's case, which may serve to throw some light on the nature of this thyroid tumefaction. The circumstance I allude to is, that from an early period of the disease a remarkable disproportion was found to exist between the beats of the radial and the carotid arteries, the pulsation of the former being comparatively feeble, while those of the latter were violent, causing a most evident throbbing of the neck, and accompanied by a loud rustling sound. In about fourteen months the heart presented all the signs of Laennec's passive aneurysm; the tumor in the neck is subject to remarkable variations in size, sometimes diminishing nearly one-half. None of her family have had goitre, nor was she ever in any of the usual localities of the disease."

This description is sufficiently concise and sharp to make one realize that as a lecturer, Graves must have been distinguished by force and clearness of language. This impression is well substantiated by his clinic on the treatment of fevers. "In a patient laboring under fever and a protracted abstinence from food, whose sensibilities are blunted and whose functions are deranged, it is not at all improbable that such a person will not call for food although requiring it; and if you do not press it on him, and give it as a medicine, symptoms like those which arise from starvation in a healthy subject may supervene. You may, perhaps, think it unnecessary to give food, as the patient appears to have no appetite and does not call for it. You might as well think of allowing the urine to accumulate in the bladder because the patient feels no desire to pass it."

The following story illustrates how keenly he felt the truth of what he taught. He was going around the hospital one day and entered the convalescent ward. He began to expatiate on the healthy appearance of some patients who had recovered from severe typhus. "This is all the effect of our good feeding," he exclaimed, "and lest, when I am gone, you may be at a loss for an epitaph for me, let me give you one in three words: 'He fed fevers.'"

During many years Graves enjoyed a large and lucrative practice, and was much sought after as a consultant. Yet it is as a teacher, and not as a practitioner of medicine that he must be remembered. He was a strong man,

* The original paper was published in 1835.

and a bold man, capable of holding friends and enemies. He came to Ireland at a time when medical education in that country was at lowest ebb, yet by his efforts he made the Dublin School universally known, and exercised a great influence on medical teaching in England, France and America. His own words are his best epitome, "If a teacher neglects his duty, if he teaches erroneously, his negligence and his error are multiplied indefinitely by those whom he ought to have better instructed; the scene of his guilt, for it deserves no better name, becomes fearfully enlarged, for there is no country so remote that it may not contribute victims to the incapacity of his pupils. But if, on the contrary, he works with zeal and diligence, a compensation awaits him to which scarcely any member of any profession can attain."

He died in 1853.

Carl Adolphus von Basedow was born in Dessau in 1799. His father was a government councillor and his uncle a distinguished teacher. Thus he, as well as Parry and Graves had the advantages of comfortable surroundings and a good up-bringing. He attended school in his native city but went to Halle University to learn medicine.

The University of Halle was the first of the German universities to be founded on the principle of free research and instruction. The older teaching was based upon the assumption that the truth had already been given, and that instruction had merely to do with its transmission. In Halle, however, it was believed that the truth must be discovered and that it was the duty of a college to qualify and guide the student in this search. Von Basedow fell under such influences.

After graduation in 1821, he moved to Merseburg. The town is one of the oldest and most picturesque in Germany; it is situated on the river Saale, and has always been small and unprogressive. Its most striking features are its cathedral, its town hall and castle. It appears to be a very typical, old-fashioned German village.

Von Basedow practised here until his death. The influence of his early training is well shown by his article on exophthalmic goitre which appeared in 1840, and is the first complete monograph on the subject. It begins by citing all the available literature that Basedow could find. He reports four cases of his own, occurring in three women and a man. All had exophthalmos and goitre, three had frequent pulse, two palpitation. Other symptoms were emaciation, dyspnea, edema, nervousness, diarrhoea and mild sweating.

He explained the exophthalmos as due to hypertrophy of the orbital tissues, "strumous" in the sense of goitrous. While his physiology and conception of the disease differed from the views now held, nevertheless, von Basedow was the first observer to attempt to study exophthalmic goitre as a disease and his article is remarkably complete. He wrote various other monographs on medicine and surgery, none of which are as well known as the one on goitre. He died in 1854 as a result of infecting himself at an autopsy on a case of typhus fever.

It is impossible to study the lives of these three men without feeling the important influence that environment had on their characters. Parry lived in the centre of fashion, and his interests were associated with those of the people with whom he came in contact. He had no university connections to stimulate him. As a result, he developed the tact in handling his patients and the knowledge of men that made him so successful. He was a broad-minded man, well informed about the variety of subjects which interest the educated Englishman who lives in the country but who deals with all classes of people. He was a splendid example of the general practitioner,* 'the flower (such as it is) of our civilization, and one who shared as little as any in the defects of the period, and most notably exhibited the virtues of the race.'

Graves lived in a university town where scholastic success represented the pinnacle of greatness. As a result the practice of medicine became to him of secondary importance. His aim was to improve the conditions for medical education in his own school and elsewhere, and his ambition was to make himself a clinical teacher. By insisting that the most essential part of a student's instruction was obtained at the bedside in close contact with the patient, he showed a far-sighted policy, carried it out, and materially changed the plan of medical teaching in England and America.

Von Basedow lived in a small German town. He was uninfluenced by the cares of a lucrative practice or the responsibilities of a university professorship. He lived his own life as an upright citizen, studying carefully the subjects that interested him, and describing them completely and well It is a pity that more details of his life and character are not known.

Whether exophthalmic goitre be called Parry's disease, or Graves' disease, or Basedow's disease, all three of these physicians deserve places in the history of medicine. It is difficult to find more perfect models of the practitioner of medicine, the teacher of medicine, or the student of medicine.

THE DEMONSTRATION OF GALL-STONES BY THE ROENTGEN RAY.

BY ARIAL W. GEORGE, M.D., BOSTON,

AND

ISAAC GERBER, M.D., BOSTON,

Assistant Physician, General Medical Department, Boston Dispensary; Visiting Physician for Gastro-Intestinal Diseases, Mt. Sinai Hospital.

UP TO within the past year, the demonstration of gall-stones upon plates by the Roentgen method has been regarded generally as a rare curiosity. Of late, however, Roentgenologists are learning more and more how to demonstrate these stones, so that the examination may be of definite diagnostic and prognostic value to the practitioner.

We believe that this advance has been peculiarly an American one. Carl Beck showed the first plates of gall-stones at a meeting in New York in 1899.[1] Since then he has devoted considerable energy to a development of the technique of gall-stone Roentgenography. More recently Case[2] and Cole[3] have both published numerous cases of gall-stones.

The practical application of the Roentgen method to gall-stone diagnosis has apparently not spread so rapidly on the other side of the Atlantic. Ewald, in his very recently published monograph on diseases of the liver,[4] states that—"unfortunately radioscopy has, up to the present, given us no reliable data for the recognition of gall-stones. The few cases that have been demonstrated were all rare exceptions of pure calcium stones."

This statement is by no means true as regards the present status of gall-stone diagnosis in this country.

In our own experience we began to find the shadows of gall-stones by accident during the course of the bismuth examinations of the alimentary tract. Gradually the accidental findings became so frequent that we found it advisable to look for gall-stones in every case. At present we have adopted the routine method of examining the gall-bladder region in every patient, before giving the bismuth meal.

Pure cholesterin stones, as is well known, do not have a density differing much from that of the general abdominal contents; therefore they will not interrupt the Roentgen Rays to any appreciable degree, so that their shadows cannot be differentiated. Fortunately however, these pure cholesterin stones are not common,[5] or at least do not cause many chronic disturbances. When the gall-bladder is chronically inflamed with repeated infections, the stones that are deposited have the characteristic lamellae of calcium and bile salts encrusted on the cholesterin core. It is only the calcium admixtures that we can show by the Roentgen Ray. Therefore, the clearness of demonstration of gall-stones upon the plates will be in proportion to the amount of calcium present.

As a rule nearly every case which has symptoms referable to gall-stones will have some calcium.[5] Of course the Roentgen demonstration of gall-stones has not yet reached the position that has already been attained with regard to renal and ureteral calculi. However, at present we believe that with care, and with attention especially directed to the gall-bladder region, gall-stones can be demonstrated in nearly every case where the symptoms have been of long duration, and gall-stones are really present.

In the near future we hope that the certainty of diagnosis will approach that which already has been reached with renal calculi. At any rate, before long it will be possible to state definitely whether there are gall-stones present containing calcium or not.

The technique for the demonstration of gall-stones is very simple. The complicated methods which have been devised for projecting away the liver shadow, etc. are entirely unnecessary. The patient lies upon the table with his face down. The plate is placed under the right hypochondriac region. The maximum of sharp definition is obtained with a very small diaphragm, 1½ inches in diameter, and a very small cylinder placed close down upon the back. It is preferable to use a fairly soft tube with a rapid exposure. It is better not to use intensifying screens, but to use the simple plates as in kidney work.

The gall-stone shadows will vary according to their calcium content. Often there will be a central light area due to the cholesterin core, with a peripheral calcium shadow. (Fig. 1.) Occasionally there may be made out the irregular deposits of calcium corresponding to the lamellated structure. (Fig. 1, stone 2.) At times the shadow will be dense and almost uniform, when there is considerable calcium salt present. (Fig. 2.) As a rule the faceted outlines will

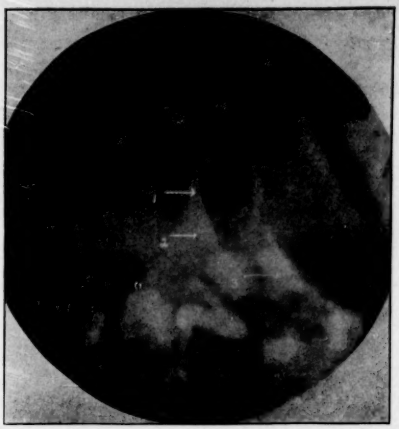

FIG. 4.—1. Large conglomerate mulberry stone, with numerous areas of calcification.
2. Edge of gall-bladder.
3. Edge of liver.

FIG. 5.—1. Mass of nearly forty small gall-stones.
2. Antrum of stomach, demonstrated by fluoroscope to be adherent to gall-bladder region.
3. Pressure effect of gall-bladder upon antrum.

FIG. 6.—Arrow points to mass of ossified rib-cartilage. This was probably the site of an old injury to the cartilage.

be clear, although at times the calcium masses may be circular or irregular. The stones will sometimes be closely packed in a mass, corresponding to the gall-bladder boundaries. At other times the shadows may be more separately scattered throughout the gall-bladder region. When the faceted outlines are distinct, it is easy to tell that there are many stones present. However, when the shadows give the appearance of a single conglomerate mass, one is easily led into error. We have seen essentially the same picture prove in one case (Fig. 4) to be a single conglomerate stone of the mulberry type, and in another case it proved to be a mass of closely packed small stones. (Fig. 5.) The shadows of gall-stones may, in rare instances, be entirely obscured by a very greatly thickened gall-bladder.

In addition to the gall-stones, we are usually able to show other indirect evidences of gall-bladder disease, by the later bismuth examination. These consist of the evidences of adhesions due to pericholecystitis. The duodenum and antrum of the stomach occupy an abnormal right sided position in the sub-hepatic region, and on manipulation appear to be fixed there. (Fig. 5.) The hepatic flexure, or some parts of the proximal transverse colon, may be demonstrated as adherent to the gall-bladder. (Fig. 1.) However, these accessory aids merely mean adhesions in the gall-bladder region. They may be congenital adhesions, or the results of chronic gall-bladder disease without stones. The actual demonstration of the gall-stones themselves establishes the diagnosis without a doubt.

The commonest sources of error in the diagnosis of gall-stones are renal calculi, calcified mesenteric glands, and costo-chondral ossification.

Renal calculi usually cause confusion when we do not find the characteristic light cholesterin cores and faceted outlines, or when we have single or conglomerate stones. The writers have, however, seen renal calculi that showed definitely faceted outlines, and on a single Roentgen plate could easily be interpreted as gall-stones. The differentiation can usually be made by taking similar plates with the patient lying first on his abdomen and then on his back. Gall-stones are nearer the anterior abdominal wall, while renal calculi are nearer the back. Therefore the anterior plates in the case of gall-stones will show the shadows small and sharp, whereas the plates taken on the back show the shadows larger and more blurred. Just the reverse occurs in the case of renal stones; that is, the posterior plates show smaller and sharper shadows than the anterior plates. The shadows of renal calculi usually bear a constant relation to the kidney outline, whereas those of gall-stones may change their relative position with changes in the projection angle.

Calcified mesenteric glands will be found to occupy somewhat different positions in different plates, by manipulating the abdominal contents between exposures. As a rule they are found much lower than the gall-bladder region. Also there will be found very little difference as regards the postero-anterior, or the antero-posterior exposures.

Ossification of the *costal cartilages* may produce a calcium mass simulating a number of gall-stones. (Fig. 6.) On careful observation, however, this mass will be found continuous with the ends of the ribs, and also similar masses will usually be found in the left hyprochondriac region.

In our routine work, gall-stones have been found in cases where their presence was at first entirely unsuspected. Later a careful history has brought out symptoms attributable to them. Again they have been found in cases where the entire attention of the physician had previously been directed to their secondary manifestations in the stomach or bowel. In these cases no symptoms of gall-bladder trouble could ever be elicited. This has been especially true in several cases of anacidity, and one of true achylia, resulting from gall-bladder disease. We therefore believe that a routine examination of the gall-bladder region is of considerable importance as a preliminary to the later bismuth examination of the alimentary tract.

SUMMARY.

The demonstration of gall-stones by the Roentgen Ray has already reached a position in this country that warrants its more general use as a dependable aid to diagnosis.

It is advisable to examine the gall-bladder region for stones prior to every bismuth examination of the alimentary tract.

We believe that gall-stones can be demonstrated by the Roentgen Ray in nearly every case of gall-bladder disease of long standing where stones are really present.

The chief sources of error are renal calculi, calcified mesenteric glands, and costo-chondral ossification. These can be differentiated by proper technique.

INTRACRANIAL HÆMORRHAGE IN THE NEWBORN.*

BY ROBERT M. GREEN, M.D., BOSTON.

[From the Clinic of the Boston Lying-in Hospital.]

INTRACRANIAL hæmorrhage in the newborn either may be due to the trauma of labor, natural or instrumental, or may be associated with the disease known as *haemorrhagica neonatorum*. In the former instance, the treatment is purely local; in the latter, the local treatment becomes secondary to that of the general condition. In either case, early recognition of the symptoms is of extreme importance, since any operative treatment, if indicated, must be prompt to be effective. This review of the subject will be illustrated by cases from the clinic of the Boston Lying-in Hospital, for the privilege of observing and reporting which I wish herewith to express my grateful acknowledgment to the Visiting Physician.

Trauma, especially of difficult forceps delivery through a contracted pelvis, has long been recognized as the commonest cause of intracranial hæmorrhage in the newborn. There may be little or no external evidence of injury; the baby usually seems normal in every way; and symptoms of its condition seldom appear before the second day, and sometimes not until the fourth or fifth, probably depending on the amount and rapidity of the hæmorrhage. As a rule the latter is usually venous, and of slow oozing character. The signs, which theoretically should be those of progressive increase of intracranial pressure, are seldom typical, as in an adult, but are often modified into a clinical picture, which, though distinct and definite when once recognized, is not that which *a priori* one would expect.

Abels[1] emphasizes the similarity of this picture to that of traumatic tetanus. He points out, however, that strabismus and nystagmus are often absent in hæmorrhage, and that the extent of the convulsions is seldom as great as in tetanus. In my experience the reflex and motor phenomena are frequently unreliable guides to diagnosis or as localizing signs. The two following cases may serve to indicate the type of clinical picture more often met in traumatic intracranial hæmorrhage due to forceps extraction.

CASE 1. Baby S. (B. L. H. 149-92. No. 16570). Male. Born March 31, 1909, by difficult multiparous high forceps extraction. Weight, 9 lbs. 13 oz. Easily resuscitated. Appeared normal and nursed until 48 hours old, when it began to refuse the breast. Its cry, previously lusty, became feeble and querulous. Physical examination showed marked general pallor of skin and mucous membranes. Face slightly puffy. No bulging of fontanelles. No alteration of reflexes. No external hæmorrhage. Thorax and abdomen normal. The baby was stimulated with heaters and brandy, but died in a few hours without development of further symptoms. Post-mortem examination: The right cheek anterior to the right ear, and the left cheek in the corresponding situation, show a broad purplish area of discoloration. On section, the tissues of the scalp are found infiltrated with a considerable amount of blood-like material. This infiltration is continuous with a similar condition in the subcutaneous tissues of the upper part of the areas of purplish discoloration described above. There is no break in the continuity of the tissues along the sutures, and no bulging of the fontanelles. On opening the skull, a large amount of fluid blood escapes from beneath the dura, and on removing the brain the convexities of the hemispheres are found covered with a rather thick layer of blood-clot. This is situated mainly in the region of the posterior half, but it extends forward laterally as far as the temporal lobe. At the base, there is a slight amount of clot along the crura and over the pons. On section, the brain tissue is not remarkable. The sinuses, as far as can be made out, are intact, and the hæmorrhage is probably due to a break or breaks in the pial vessels. The trunk was not examined.

CASE 2. Baby P. (B. L. H. 152-46. No. 16906). Female. Born August 29, 1909, by difficult forceps extraction through a contracted primiparous pelvic outlet. Weight, 7 lbs. 10 oz. Baby easily resuscitated and cried vigorously. Face considerably traumatized. No cephalhematoma. Nursed well until the fourth day, when it began to refuse the breast, and to develop general pallor and progressive œdema of the right side of the face. Cry feeble and moaning. Physical examination was entirely negative. Lumbar puncture yielded clear fluid. The baby was fed breast milk with a medicine dropper and stimulated with brandy and subpectoral salt solution, but continued to fail, and died, without convulsions, on September 5.

Post-mortem examination: On the right side of the head, the tissues are swollen and show dark reddish discoloration. On section, the subcutaneous tissues are swollen and markedly infiltrated with brownish red, bloody fluid. No fractures of the skull are made out. The sutures are intact. On opening the skull, there is a moderate amount of frank blood-clot resting here and there over the right hemisphere, and a considerable amount of blood-like material in the right middle fossa. This blood is all subdural. No definite laceration of brain-tissue is made out. The sinuses are intact. Trunk: the peritoneal cavity is not remarkable, and the stump of the umbilical cord is in good condition.

It appears from these cases that subdural hæmorrhage of fatal grade may occur without producing the classic signs either of intracranial pressure or of traumatic tetanus. Indeed, I have come to feel, from observation of over a dozen cases, that, given an adequate history, a presumptive diagnosis of intracranial hæmorrhage may be made in any baby that, within a few days of birth, becomes pale, refuses the breast, and shows a peculiar, though slight, facial œdema. This latter sign, presumably due to back pressure from within the skull on superfi-

* Read at a meeting of the Surgical Fortnightly Club on Feb. 24, 1914.

cial veins emptying into the dural sinuses, I have felt to be a sign of considerable importance and value. This presumptive diagnosis may be made even in the absence of nystagmus, bulging of the fontanelles, or reflex modifications. Indeed nystagmus is so often present in babies that for this purpose it seems to me a sign of very little significance. The appearance of any of these, or the onset of convulsions, is of course confirmatory evidence.

Types of Intracranial Hæmorrhage. (Seitz.)

Fig. 1. Intraventricular Hæmorrhages.

Fig. 2. Massive Subdural Supratentorial Hæmorrhage of the Cerebral Convexity.

For further confirmation, lumbar puncture is important, and should generally be done; but even this may fail to yield bloody fluid in the presence of considerable hæmorrhage. Whether it does so or not, probably depends on whether the hæmorrhage is confined to the convexity of the cerebral hemisphere or extends below the tentorium and along the base.

For complete confirmation, aspiration of the subdural space, through a fontanelle or suture, is of supreme value, and should be done in every suspected case, and always before any operative measure is undertaken. This procedure is advocated by Henschen,[2] its originator. It is not only of diagnostic but may be also of therapeutic value. Gilles[3] reports a case cured by "decompressive cranial puncture." The technic is simple. Care must of course be taken not to wound the dural sinuses. Over the vault of the cranium there is abundant room, especially when the subdural space is filled with blood. The needle should be inserted nearly parallel with the surface of the skull, and when entered, if blood is not immediately obtained, may be carefully swept in various directions, not, however, attempting to cross the middle line, on account of the falx. The coronal suture, at the lateral angle of the anterior fontanelle, is the most favorable point for insertion; but exploration may also advantageously be made through the lambdoid suture. If blood be found, as much may be removed as can be made to flow through the needle, depending on the degree of coagulation.

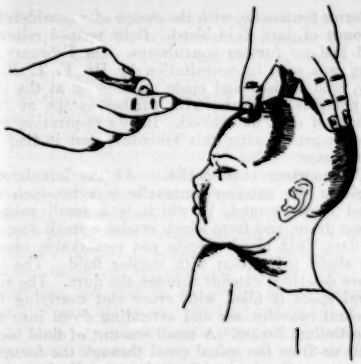

Fig. 3.

Technic of Fontanelle Puncture. (Henschen.)

If a considerable amount of blood can be withdrawn in this manner, it may be wise to wait before instituting further procedures. But if only a small amount be obtained, or if there be no improvement in the baby's condition, immediate decompressive craniotomy is indicated. Of cases thus treated, 17 have thus far been reported, 9 by Cushing[4], 1 by Seitz[5], 1 by Meara and Taylor[6], 1 by Hubbard,[7] 3 by F. T. Murphy,[8] and 2 by Simmons.[9] Of these, 7 have recovered, four of Cushing's cases, 1 of Murphy's and 2 of Simmons's. Torbert,[10] in 1909, reported two cases, both of which, however, died without operation.

The operative technic, as described by Simmons, consists of a transverse skin incision along the coronal suture. The suture itself is then opened and the dura incised, first on one side, then on the other, of the median line. If necessary, the suture incision can later be extended to make an osteoplastic flap, but often mere incision, with insertion of a rubber-tissue wick, affords sufficient drainage. Both of Simmons's cases recovered under this treatment, and it seems that perhaps others have died from the greater shock of a more extensive procedure.

That fatal intercranial hæmorrhage should result from difficult forceps delivery is not surprising; indeed the wonder is that it does not occur more often. But that it should follow easy, normal, even multiparous labor is almost incredible. Yet such is the fact, as is evidenced by the two ensuing cases:

Case 3. Baby L. (B. L. H. 153-32. No. 17257). Female. Born January 30, 1910, after a spontaneous precipitate primiparous labor of 4 hours, 10 minutes, through a slightly justo-minor pelvis. Weight, 6 lbs. 14 oz. Baby easily resuscitated and cried vigorously. Continued well until February 4, when it had two convulsions. Physical examination showed moderate bulging of the anterior fontanelle, but was otherwise negative. A hypodermic needle was inserted into the lateral angle of the

anterior fontanelle, with the escape of a considerable amount of dark fluid blood. Baby seemed relieved and had no further convulsions. On February 5, baby was seen in consultation by Dr. F. T. Murphy, who advised and made an incision at the site of previous puncture, with further escape of two ounces of dark fluid blood. Baby's respiration and color improved after this procedure, but it died an hour later.

Post-mortem examination: At the left lateral angle of the anterior fontanelle is a two-inch incised linear wound, in which is a small rubber-tissue drain, and from which exudes a small amount of dark fluid blood. Scalp not remarkable except for slight infiltration with similar fluid. The cut above described extends through the dura. The subdural space is filled with cruor clot overlying the cerebral convolutions and extending down into the longitudinal fissure. A small amount of fluid blood wells up from the spinal canal through the foramen magnum. Cerebral sinuses intact. Brain otherwise normal in appearance, and on section shows no hæmorrhage into its ventricles or substance. Examination of trunk showed nothing abnormal.

CASE 4. Baby C. (B. L. H. 156-50. No. 17386). Male. Born March 29, 1910, after an easy, normal, multiparous labor of 16 hours, 10 minutes, through a slightly justo-major pelvis. Weight, 9 lbs. 8 oz. Easily resuscitated and cried vigorously. Appeared normal and nursed well until April 1, when it refused the breast. The temperature was 100°, the anterior fontanelle slightly prominent, but physical examination was otherwise negative. That afternoon the temperature rose to 101°, the fontanelle became more prominent, and spasmodic nystagmus developed, but there were no convulsions. The general condition remained good, but on April 2 the baby had a convulsion and died before any treatment could be instituted.

Post-mortem examination: Scalp normal. Fontanelles and sinuses normal. Subdural space contains a small amount of fluid blood, especially on the right side, increasing in quantity towards the posterior part of the brain. The right occipital lobe is largely replaced by a massive currant-jelly clot, about the size of a hen's egg, and homogeneous throughout. The source of this hæmorrhage could not be determined. The remainder of the brain was normal on section. Examination of the trunk showed nothing remarkable, except some minute punctate hæmorrhagic patches in the lungs.

The precipitate labor in the first of these cases may have been a sufficient traumatic factor to explain the hæmorrhage; but in the second there seems no adequate reason to account for it. It is noteworthy that in none of the cases of this series could the source of the bleeding be determined at autopsy. Beneke[11], [12], in 1910. expressed the belief that in the majority of instances the lesion is a laceration of the tentorium. Pott,[13] in 1911, reported 33 autopsies on the newborn, in which tentorial lacerations were found. He describes three types of tear: one in the free edge of the tentorium, one in its superior layer, and a third between the layers. He ascribes them to the tension put on the tentorium by the compression of parturition, which stretches the falx in the direction of the long axis of the skull.

Henschen,[14] in 1912, concurs with Beneke's opinion, but points out that in cases where such lesion is absent the bleeding probably comes from the rupture of veins in the pia. Bauereisen[15] reported two and later[16] nine cases of tentorial laceration. Benthin[17] reported 10 cases, and expressed his belief that in normal deliveries the lesion may be produced by too violent manual compression of the head through the perineum in the effort to save the latter from tearing. Von Herff[18] also reports a case and believes the lesion to be often of this type.

Seitz[19] believes that only in about half the cases is the intracranial hæmorrhage due to tentorial laceration. In some of the others in which the hæmorrhage is intraventricular, instead of subdural, he believes the bleeding is from the veins of the choroid plexus. Eastman[20] has reported such a case, in which there was intraventricular as well as subdural clot. In the remainder, that is in supratentorial hæmorrhages over the cerebral convexity, Seitz believes the source is from lacerations of the superior longitudinal sinus or its tributaries. He believes also that venous stasis and increased fœtal blood-pressure are important determining or predisposing elements in intracranial hæmorrhage of all types.

Finally, it is to be remembered that intracranial hæmorrhage may be merely one localization of the bleeding of *hæmorrhagica neonatorum*, as the following cases illustrate.

CASE 5. Baby B. (B. L. H. 171-176. No. 19245). Male. Born June 24, 1912 after a normal, easy multiparous labor of 13 hours. Weight 9 lbs. 8 oz. Baby easily resuscitated and cried vigorously. Apparently normal except for cephalhematoma below posterior fontanelle. Nursed well until June 28, when it began to refuse the breast and showed marked pallor. On June 29 the baby was listless and very anemic. The hematoma on the back of the head had increased to twice its original size. The pupils were dilated and did not react to light. The left knee jerk was markedly increased. Both hands in position of tetany. Twitching of eyelids and lips, but no true convulsions. On June 30, there appeared small hæmorrhagic spots on the skin under the right axilla, on the left arm and over the middle of the back. Seen in consultation by Dr. Vincent, who injected 10 c.c. of mother's blood subcutaneously into the baby. Four hours later 10 c.c. of blood were similarly injected. The baby showed no improvement, but sank into progressive coma and died on July 4.

Post-mortem examination: There were several c.c.of bloody fluid in the pericardium. Each adrenal was reduced to a single large cyst containing bloody fluid. There is over the occiput a flaccid mass, the size of half a peach, which consists of diffusely infiltrated blood-clot extending forward in the median line to the anterior fontanelle. It lies under the epicranial aponeurosis, covering the squamous portion of the occiput, and not connected with the interior of the cranium. On opening the skull, a

free subdural blood-clot was found overlying the entire right hemisphere and extending along the base into the spinal canal. Source of hæmorrhage not determined.

Case 6. Baby Y. (B. L. H. 172-206. No. 19379.) Female. Born Aug. 22, 1912, after a precipitate multiparous labor of two hours. Weight, 7 lbs. 14½ oz. Baby easily resuscitated and cried vigorously. The mother's four previous pregnancies all terminated in miscarriage, but her Wassermann reaction was negative. The baby nursed well at first, but lost weight steadily. There was slight bleeding from the vagina a few days after birth. On Sept. 2 there was a slight hæmorrhage from the mouth, and on Sept. 3 a bright, profuse hæmorrhage from the cord. There was slight ptosis of the left eyelid, and paresis of left half of the body. Seen in consultation by Dr. Vincent. Anterior fontanelle bulging; lumbar puncture yielded 5 c.c. of blood-stained fluid. Thirty c.c. of blood were taken from the mother's vein and injected subcutaneously near the baby's scapula. There was no improvement, and the baby died on Sept. 4.

Post-mortem examination: Considerable fluid blood oozing from umbilicus, which is open and communicating with the umbilical vein, the stump of the cord being gone. There is slight oozing of bloody fluid from the mouth and nose. On reflection of the scalp, the anterior fontanelle, the sagittal and coronal sutures were seen to be dark and tense, and on incision the subdural space was found to be occupied by a diffuse layer of blood-clot, somewhat thicker on the left hemisphere than on the right, and extending completely around to the base of the skull, and down through the foramen magnum into the spinal canal. Source of hæmorrhage not determined.

It may perhaps be questioned whether the first of these two cases were really one of true hæmorrhagic disease, though it was so considered by Dr. Vincent. The second, however, was undoubtedly so. In both cases, the treatment employed by Dr. Vincent was directed toward relief of the anemia. Even had transfusion been possible, this alone would not have sufficed in the presence of so massive an intracranial effusion. In an ideal case of this type, one might first transfuse to restore the volume of blood and correct the tendency to hæmorrhage, and then aspirate or decompress to relieve the intracranial tension.

Obviously the most important measure in connection with so serious a condition as intracranial hæmorrhage is prophylaxis. In cases associated with hæmorrhagic disease this is manifestly impossible: a slight and otherwise unimportant degree of unavoidable trauma may here act as an inevitable factor in determining the location of an impending hæmorrhage. In normal deliveries one should remember not to compress the head too violently with the hand through the perineum, in the effort to save the latter from tearing. Above all one should, when possible, avoid all difficult or high forceps extractions by doing elective Cæsarean section. This of course requires rare judgment, since it is a matter of great difficulty to tell in advance how easily a given fœtal head may pass through a given pelvis. In weighing arguments for decision, however, due consideration should be taken of the much greater risk of intracranial hæmorrhage in high forceps deliveries, particularly where the fœtal life is a matter of special importance or solicitude.

Doubtless minor grades of intracranial hæmorrhage, from which the baby recovers spontaneously, often occur unrecognized. Of the possible or probable sequels of such non-fatal cases in epilepsy, spastic paralyses, imbecility, or other defects it is not practicable here to speak. In severe cases of intracranial hæmorrhage, the prognosis for life is so grave as to demand prompt recognition and efficient treatment of the condition. In all cases the prospect of complete functional recovery is so uncertain as to demand the most zealous prophylaxis.

While the above paper was in press, I had the opportunity and privilege of seeing at the Boston Lying-in Hospital and operating on the following additional case.

Case 7. Baby K. (No. 20718.) Male. Born March 30, 1914, after a protracted multiparous labor, terminated by low forceps. Weight, 8 lbs., 6½ oz. Baby easily resuscitated and cried vigorously. It seemed healthy at first, but never took its feedings well and lost weight steadily. I first saw the baby on the morning of April 12. At that time it had a pinched, anxious, trismic expression. The arms were spastic and held in a typical position of tetany. The right knee-jerk was exaggerated, the left could not be elicited. The pupils were equally dilated; the eyes showed moderate nystagmus and were generally held directed towards the right. There was marked bulging of the anterior fontanelle. A diagnosis was made of supratentorial intracranial hæmorrhage, probably on the left side, and was confirmed by cranial puncture. Clot was obtained on the left side, and a small amount of bloody fluid on the right. That afternoon, as soon as parental consent could be obtained, the baby was operated on by Dr. Simmons's method. A small amount of clot and a considerable ooze of bloody fluid was obtained from the incision through the left fronto-parietal suture, and a small amount of similar fluid from the right side. Rubber tissue drains were placed into the subdural space on both sides, and the skin wound closed with interrupted horsehair stitches. A moist salt solution dressing and bandage were applied and the baby sent to the ward in poor condition. The bulging of the anterior fontanelle was entirely relieved by this procedure, and the pupils became contracted; but the baby continued to refuse feedings, and died in a few hours. Post-mortem examination showed a moderate supratentorial hæmorrhage, chiefly restricted to the left side, with a small amount of blood on the right side and base, which was apparently due to leakage from above. The source of the hæmorrhage could not be determined.

Though this case differs somewhat in type and duration from those above reported, it illustrates essentially the same principles of diagnosis and treatment. If the condition had

earlier become apparent, operation might possibly have been more successful.

CONCLUSIONS.

1. Intracranial hæmorrhage may occur in the newborn either from the trauma of operative or normal labor or in association with *haemorrhagica neonatorum*.

2. It often does not present the typical clinical picture of increased intracranial pressure.

3. Its presumptive diagnosis depends on early recognition of refusal to nurse, pallor, and slight facial œdema, which may be confirmed by the appearance of more classic signs.

4. Diagnosis may be positively established, and some therapeutic relief afforded, by lumbar puncture (when the hæmorrhage is infratentorial), or by cranial puncture (when the hæmorrhage is over the cerebral convexity).

5. If these measures fail to give relief, operative decompression by craniotomy is indicated.

6. The majority of intracranial hæmorrhages in the newborn are subdural, but intraventricular hæmorrhages may also occur.

7. The source of bleeding may be from laceration of the tentorium, of the choroid plexus, of the longitudinal sinus or of the pial vessels.

8. In cases associated with hæmorrhagic disease preliminary transfusion may be indicated before craniotomy.

9. The gravity of the prognosis demands an enlightened prophylaxis by avoiding all unnecessary occasion for fœtal trauma.

SOME PRESENT PROBLEMS IN TUBERCULOSIS.*

BY P. C. BARTLETT, M.D.,

Late Superintendent Rutland State Sanatorium.

THE last report of the Boston Association for the relief and control of tuberculosis shows a constant decrease in the number of deaths from tuberculosis during the past five decades. That there has been a decrease is gratifying, but there is still a great deal of work to be done.

* Read at the sixth Massachusetts Conference on Tuberculosis, March 26, 1914.

In this paper I shall briefly discuss the following problems.

First, the number of consumptives in the state and the number of beds available.

Second, the reason for the scarcity of comparatively early diagnosis.

Third, methods to bring about the early discovery of incipient cases.

Fourth, the question of suitable occupations for arrested or partially arrested cases of tuberculosis.

Fifth, the danger of duplication of effort in the various health boards, local societies, etc.

There are at present in Massachusetts approximately ten thousand patients under treatment for tuberculosis, and there are many times this number of people with non-active tubercular foci. We have about 3000 beds in the different sanatoriums and hospitals that can be used for these patients.

There is a considerable number of these cases that do not need hospital or sanatorium care as they can be perfectly well looked after in their own homes. There is still a large number of cases that need hospital care for which we have no provision. Many of these should be taken care of in their own communities, in hospitals built for the advanced type of cases. And when such hospitals are provided one of our present problems will disappear.

There are still altogether too many patients with active disease that are not recognized as tuberculous until their disease is moderately advanced or worse. There are two causes for this delay. First, many patients do not seek advice because of lack of knowledge of their complaint. Second, patients seek advice but their physician delays making a diagnosis because of lack of knowledge of the early symptoms or because of a too hurried examination.

For the first class of cases we must continue our educational campaign and, if possible, discover new methods of bringing before the people the necessity of early diagnosis. Dr. H. L. Barnes, in a recent paper, advocated newspaper advertising to bring the matter before the people and I believe this would help.

For the second class of cases we should perfect ourselves in every way possible to make an early diagnosis and also see that the medical students are given practical instruction in this most important branch of internal medicine. In our zeal to find the early case we should not, however, make a positive diagnosis of clinical tuberculosis without sufficient evidence. There is a distinct Phthisiophobia in the community to be combated and this can only be done by education.

We must recognize the fact that a tuberculous focus has been established in the majority of children and that they will react to a tuberculin test, but show no evidence of clinical tuberculosis. The problem is to prevent them from becoming active infections and to decrease

the number that are exposed to infection in infancy and childhood. The children should be placed in the best environment possible and the cases of apparent poor physical development especially looked after, kept in open air schools or open air rooms, and live in hygienic surroundings. The sociologist says, "Provide an income sufficient to obtain good food and proper housing and there will be fewer cases of tuberculosis."

Another problem which always confronts us is to find suitable employment for the arrested or partially arrested case of the disease. Many patients do better to resume the occupations for which they have been trained rather than to take up some entirely new occupation even if their work is to some extent undesirable, provided they can live a well-regulated, hygienic life when not at work. There are some cases, however, that could be distinctly benefited if they could be trained in some light out-of-door employment or some of the less dangerous of the indoor employments. Last year the legislature of New York passed a bill allowing the municipal hospitals to establish work shops. These work shops are for the production of articles or supplies needed in the institution itself or by any other department of the municipality. This offers one method of training patients in occupations which are frequently better than the one in which they are trained and also starts them at work under the best possible conditions.

There is also a problem of duplication of effort. The local boards of health, the various tuberculous societies and various other health agencies should realize that only through the most complete co-operation can the best results be obtained. Miss Billings, who is employed by the Trustees of Hospitals for Consumptives, is at present doing valuable work in looking up discharged sanatorium cases and in securing the co-operation of the local boards of health and local societies.

Some of the problems, then, that confront the tuberculosis worker are very complex and are bound up with the problems which confront all of the workers in preventive medicine. When we realize that about 80% of all deaths are due to preventable causes, or in other words each one of those deaths is the result of ignorance or carelessness, then we realize that only by the broadest kind of education and the union of all of our sociological, educational, medical and sanitary forces can the preventable diseases be reduced to a minimum.

A LIVING CENTENARIAN.—Mrs. Lydia Dow French, of Roxbury, Mass., is said to have been born on April 21, 1814, at Seabrook, N. H., and celebrated last week her supposed centennial anniversary. She is a widow and has two living daughters. Her health is excellent.

THE TUBERCULOUS CHILD.*

BY CLEAVELAND FLOYD, M.D., BOSTON,

Director, Out-Patient Clinic, Boston Consumptives' Hospitals Department.

SINCE the conception of the campaign to suppress tuberculosis was inaugurated three distinct steps have been noticeable in its development. At first the early diagnosis of pulmonary tuberculosis was considered to be the chief aim of most of the effort put forth. The second step has been the effort directed toward an adequate provision for those suffering with the disease in its advanced form, and thirdly, the child as an important factor in the problem has slowly become recognized. Not that the early detection of the disease and provision for it are any less important, but the question of tuberculosis of childhood has become more so.

The tuberculous child is of interest and importance chiefly from these aspects, namely, the source of and the manner in which infection takes place; the extent to which the children of the community are infected, and the influence of tuberculosis acquired in childhood upon later life.

Recent researches in the past ten years have shown that from five to ten per cent. of all cases are due to infection through milk, this type generally showing itself as tuberculosis of the joints, peritoneum or glands.

With the elimination of the tuberculous cow as a source of food this source of disease will be suppressed. Hess, in a striking observation made on infants, found that a few weeks' exposure to tuberculosis gave rise in most instances to the disease. Young children are not found to have as marked a degree of susceptibility as infants and with increasing years the intensity and duration of exposure to tuberculosis must be more marked to give rise to infection. The marked sensibility of the infant makes for a generalized tuberculosis. At an older period, general glandular infection is present, and only as the child moves on toward adolescence is the localized pulmonary infection predominant.

The entrance of the tubercle bacilli into the body takes place in two ways, through the digestive tract and by means of inhalation.

Experimental work on animals has clearly demonstrated that the organism may pass through the intestinal wall, gain access to the glands and reach the root of the lungs.

Lodgment of the bacillus in the tonsils may show subsequent inflammation of the glands of the neck with an extension into the chest.

But while the method of infection may occur from the use of tuberculous milk and the carrying into the mouth of material contaminated with the tubercle bacillus, laboratory and clinical findings still support the view that the great avenue of pulmonary infection is through direct

* Read at the sixth Massachusetts Conference on Tuberculosis, March 26, 1914.

inhalation. With the tubercle bacillus finding egress from the body chiefly from the air passages, with these secretions constantly thrown into the air, in a moist or dry state, and with the most susceptible part of the body open to the disease, it is but natural that the pulmonary tissue should be most often involved. The seat of the disease in the child may be the root of the lung and therefore not evident, except as it shows itself in symptoms of general debility.

The extent to which tuberculosis is prevalent among infants and children has been largely determined. Medin found that among 7000 children dying from various diseases, under one year old, 10% showed tuberculosis. This proportion rapidly increases with the increasing age of the child until at 16 years it is very probable,—as shown by laboratory and clinical methods that very few have not become infected to some degree.

The proportion of cases among children who have come in contact with active tuberculosis in the home varies from 29% to 40%. Sachs in Chicago obtained a percentage of 29. In Boston among 1000 children so exposed, 35% showed evidence of pulmonary involvement.

The effect upon the health and life of a child infected with tuberculosis may be evident in two ways: the immediate result may be a period of poor health, consisting of anemia and lack of strength, often with recovery, but with a very slow return to robust health, which is frequently never obtained. In a much smaller number of cases the lungs may be extensively involved and the child present the picture of phthisis as commonly seen in the adult.

In a great majority of cases, therefore, in early life, the tuberculous infection merely shows itself as a state of chronic ill health or general debility. With the advent of young adult life, necessitating occupation in a workshop or factory, the disease often seems to manifest itself for a second time either through the lighting up of the old process or by an added infection from outside contact. It is probable, however, in many instances where the patient in childhood has been infected and has yet grown to be a robust adult, this very early infection acts as a preventative in that the body is more resistant to a subsequent infection.

In those instances also in which a second attack of the disease occurs, the extent of its damages may be much more readily limited than would otherwise be the case.

Children who have attained adult years without having previously been infected with tuberculosis, and at this time of life are exposed to it, often seem peculiarly susceptible to its ravages. In these cases the disease seems to take the type of a general infection, often having a very malignant course, as is seen in infants. It is, therefore, probably true that some degree of immunity to tuberculosis is obtained through childhood infection, and if such children are subsequently surrounded with proper living conditions they may be well prepared to resist the disease, even if further exposed to it.

If, then, the child is ordinarily infected through direct contact with the disease in the home and the extent of tuberculosis in children so exposed is found to be a very large one, and that young adult life often succumbs to phthisis as a result of the lighting up of an early or later added infection, certain measures now more or less in general use in the effort to control tuberculosis should be re-emphasized. The susceptibility of young children even following limited periods of exposure has been so strikingly shown that measures looking towards the isolation of every active case of phthisis in a sanatorium or hospital are increasingly important.

Careful observation of all children so exposed for a period of years has proven of great value not only in the detection of the early stages of the disease but through the building up of the under-nourished and debilitated, has prevented a latent infection from becoming evident. For about five or six years the Boston Consumptives' Hospital has had a large number of children under observation who have in the first part of this period, shown tuberculosis acquired from home infection. At the present time the great majority of these children show little or nothing to indicate their former infection. Some are now young adults. I am confident that as a result of this prolonged period of care and observation they will prove to be well above the average in health in future years.

Medical inspection of school children is proving of great value, especially in arousing the interest of the parents in the health of the child. Many abnormal nose and throat conditions that lead to improper or prevent proper lung expansion are being corrected. The under-nourished child is supervised and the anemic child is examined for tuberculosis. Schoolhouse infection is being eliminated and along with it a better fed, cleaner and more normal mass of school children is apparent.

Some of the best work being carried on in Boston is being done by the Provident Association, where families are taught hygienic living. This necessarily means cleanliness, proper preparation of food, and fresh air in the home. This work, therefore, is fundamental in that it aims to prevent, not only tuberculosis, but disease in general. I hope the time will come when it can be greatly extended.

The recent child labor law in this state will in time undoubtedly make for better health among children and is worthy of cordial support.

If then we surround the child who has been exposed to tuberculosis in the susceptible years of life with healthful conditions in the home, healthful conditions of study, and if we prevent its early entrance into the confinement of factory or workshop life and do this on a sufficiently large scale we have the solution of the problem of the tuberculous child in our hands.

THE SOCIAL WORKER'S EDUCATIONAL INFLUENCE IN THE COMMUNITY.*

By George B. Underwood, M.D., Gardner, Mass.

Before speaking of the educational influence of a social worker in the community, might it not be well to consider for one moment what social work really is? One authority defines social work as "the study of character under adversity and of the influences that mold it for good or ill." Another says that "it is the making the best of what sound life or character there is left, also its ideals are public health and the extermination of disease."

The campaign of the social worker in Gardner is not directed against all poverty and distress, much of which comes under the province of the Associated Charities, the District Nurse, and the Overseers of the Poor, but is a campaign of education as directed to the tubercular patient, their families, and such associates as are brought into direct or constant relation with the tubercular patient. The work naturally focuses first on an active guidance of the tubercular patient that he may make the best use of such resources as he has toward recovery; and then toward the education of his immediate family and associates with the idea of preventing the further spread of the disease.

Hence, the position of the social worker is really that of teacher, as Dr. Cabot says "one who needs all the virtues, no more and no less than the railroad man, the farmer, or the shopkeeper. But his first and chief duty to all men is to give, with such ripening sympathy and friendliness as is possible under the circumstances, the benefit of his expert skill, and so fulfill his special function in the community." Besides natural versatility and tact, the work requires a fund of experience and a professional knowledge gained from a rigorous training.

Her experience and training must be varied, for the sympathetic nature which is absolutely essential, must be supplemented with a practical business training. In one family she has to teach the wage earner to plan the expenditure of his small income in such a way that necessities may be provided for his family, and again a mother must be taught the art of cooking to tempt the appetite of the patient; others need direction in the methods of housekeeping so that the patient may be surrounded by as sanitary and comfortable conditions as possible.

She must have a wide acquaintance with the business men and people of wealth in the community whose confidence she must have gained—business men, because of the dependence upon them in securing employment for those who need suitable work, and people of wealth, because of their assistance in supplying funds, with which to buy necessities and comforts for the destitute. Constant vigilance and oversight is the keynote of the work.

One not familiar with the work, would hardly appreciate the far reaching influence of the social worker. Her frequent visits to a home bring her in contact with the well members of the family whom she interests in the condition of the patient, and who thus become educated in methods of prevention of diseases as well as methods of treatment. In her numerous visits to the home she may find another member of the family in a state of malnutrition, anemia, or debility. She sends the person to the clinic or family physician for examination. No definite signs of tuberculosis are found, but with a little treatment to build him up and increase his resistance the patient is rendered less liable to the contraction and development of phthisis. This work the Association believes to be of great value.

To illustrate more vividly the influence of the social worker, let us picture an ordinary working man from thirty to forty-five years of age, who feels the full responsibility of a family from four to seven, dependent for their sustenance upon his daily work. For some time this man has felt tired, and some nights completely played out, has been subject to frequent colds, as he thinks, naturally attended with more or less cough.

Let us now imagine this man in the office of a good physician, who has been sufficiently interested in his case to have made one or more careful examinations and to have learned personal history, and who, although he has been reasonably certain of his diagnosis of tuberculosis, has just found a positive sputum.

The physician, knowing the poor home conditions and that at the present time, only a small proportion of tubercular cases can be treated at our state sanatoria, is fortunate to have at his command an efficient social worker to see that his instructions and treatment are properly followed.

The physician explains with confidence to the disheartened man that the social worker will prove an important factor in his recovery; that she will teach him not only what he can do to be of the greatest benefit to himself, but also how to avoid being a source of contagion to other members of the family, for although the physician prescribes, it is the social worker who carries out the detail of management.

The next day the social worker, having been asked by the physician to visit the patient, finds the unfortunate man thoroughly discouraged and helpless. The grief that he feels for his needy family, and the hopeless outlook into the future render him an abject figure.

The social worker enters, and on her first visit establishes a bond of sympathy and confidence. She talks with him about the instruc-

* Read at the sixth Massachusetts Conference on Tuberculosis, March 26, 1914.

tions of the physician, the necessary rest, the exercise, his food, the care of sputum, the absolute necessity of plenty of fresh air, open windows, sitting out of doors, etc., much of which seemed impossible to him as he sat in the doctor's office and thought of the lack of warm clothing and other means with which to carry out these instructions.

The social worker assures him that she can easily obtain a chair for him and plenty of warm clothing; she knows women ready and glad to sew and provide clothing for his children. So the cloud begins to lift. The confidence which the social worker inspires, arouses hope, and with new encouragement, the patient is better able to begin his battle.

It is usually at this stage that the patient with tuberculosis is the hardest to control. Oftentimes not feeling very sick, in the ordinary understanding of the term, he is inclined to wander. It is now that the frequent visits of the social worker are of greatest importance. She must be alert, earnest, convincing, and ready to correct repeated doubts the patient may have in relation to his treatment. It is now that she strengthens faith in his physician and prevents his going about from doctor to doctor in search of immediate cure.

A person but slightly ill is sometimes somewhat feeble-minded and suffers from tricks of memory with regard to the instructions and advice of the physician. In this case the patient needs constant supervision and instruction, which the physician is unable to give, but which the social worker can supply.

As I have said before, it is the incipient case which benefits most from the supervision of the social worker. A person acutely sick usually suffers pain or some distress which urges him to seek help as soon as possible. The incipient case of tuberculosis does not feel this urgent demand for relief. He may have more or less cough, suffer loss of weight and appetite, and have the sensation of general loss of strength and debility, but with proper treatment, have very little to complain about.

It is in such a situation that the patience of the social worker is taxed, for she must visit the patient frequently, see that every detail of treatment is properly carried out, and continually encourage, so that he will make the necessary effort to secure a permanent result.

Now when the patient is told and fully realizes that he has tuberculosis, his mental attitude toward the whole situation may be likened to the young man going into battle for the first time. He would run away from the enemy were it not for the watchful eye and moral support of his commanding officer. Just so does the continual moral support of the social worker bring back the confidence, and add new courage to successfully arrest and overcome the disease.

The work of the social worker, viewed from the economic standpoint rather than the humanitarian, is of great benefit to the state. If it were not for her supervision of patients returned from sanatoria, the large amounts of money expended in sanatorium treatment would in many cases be practically wasted, for it is a recognized fact that unless followed up, many patients would not continue the necessary treatment at home, and were it not for the constant vigilance and supervision of the social worker a recurrence of the disease would be sure to result. Hence, the sum expended in the treatment of the patient at the sanatorium might prove to be a loss to the state, for the patient again may soon return to his former condition.

In all this work vain indeed would be the efforts of the social worker, if she had not an advisor in the person of a good physician who is entirely in sympathy with her work, understands her needs, and is ever ready to counsel and help her in the many perplexities which are sure to arise. Without this co-operation, failure must follow where success would otherwise be attained.

Some may question—Why bother with this home treatment when out state supports institutions so well equipped for the express purpose of caring for patients? Why incur the expense of salary of a social worker and maintenance of a dispensary? The social worker watches carefully those patients who have returned from sanatoria and sends them to the dispensary or their own private doctor for examination, especially when they are taking up their work again. She follows carefully those who are waiting to go to sanatoria, and if the waiting seems long encourages them to be patient, and in the meanwhile helps them at home as much as possible.

There is a certain class of patients who do better under careful supervision at home. These cases are usually in those persons who suffer from homesickness. Take for instance a homesick person often depressed because of his condition and place him in a sanatorium where there are others afflicted as he is, and he is overcome with a sense of loneliness and homesickness. This class of cases needs the sympathy and encouragement of relatives and friends. When the patient returns from a sanatorium, he finds that the arrangement of his time has to be planned on a new basis. In adjusting himself to this new regime, the advice and moral support of the social worker is indispensable.

In Gardner, an anti-tuberculosis dispensary was established in 1909. This was earnestly and actively opposed by the physicians of the town, who in common with doctors throughout the state, at that time did not appreciate the importance of the diagnosis of incipient cases.

In 1910, the local social worker began her duties, and she was instructed to call on the physicians and see if she could help them in any tubercular case they happened to have under

observation. This plan worked so well that within a few months the physicians, seeing that the dispensary did not detract work from their offices, showed an entirely different attitude: opposition ceased, new interest was aroused, and confidence and co-operation followed. This is evident from the fact that during the first three months after the social worker commenced her duties, and the dispensary was moved to the Board of Health office, forty new cases were reported.

Since its establishment, seventy-three cases have been sent to sanatoria, seventeen of whom have died, four of these having died of other diseases than tuberculosis. Of the remainder forty-seven are working full time; eight, part of the time; and one is unable to work at all. Since 1908, 232 cases have been reported. Most of these the social worker calls upon in the interest of the attending physician or the dispensary.

Not wishing to detract from the benefits derived from sanatoria or local hospital, we wish to emphasize the effort to put more efficient social workers throughout every community in the state. We feel that as much effort should be made to put as many social workers in the field as is put into building new sanatoria, as they both are essential in the management and care of the tubercular patient.

The social worker does much to correct the mistaken ideas of the public, who sometimes practically ostracize the tubercular patient. The social worker should strive to accomplish her ends by tact, constant attention, and friendliness, rather than by making her directions compulsory and thereby creating a feeling of antagonism to her work.

That the social worker is a most important influence in a community cannot be denied, and that her influence is educational is recognized, for as Dr. Cabot says, "The contagion of disease must be opposed by a contagion of intelligence."

THE FIELD OF WORK OF THE ANTI-TUBERCULOSIS ASSOCIATION.*

By Seymour H. Stone, Boston,

Secretary, Boston Association for the Relief and Control of Tuberculosis.

THE STATE PROBLEM.

What is the tuberculosis problem in Massachusetts? Briefly stated there are about 5,000 deaths annually, and a State Commission on Tuberculosis has estimated that there are between 35,000 and 40,000 persons suffering with the disease.

* Read at the sixth Massachusetts Conference on Tuberculosis, March 26, 1914.

THE STATE PLAN FOR HANDLING THE PROBLEM.

The State has developed a well-defined policy for fighting the disease which may be summarized as follows:

1. It has established four (4) State sanatoria, to be used mainly for patients in the incipient or curable stages of tuberculosis.

2. A law was passed in 1911, and amended in 1912, providing that cities shall, and towns may, build hospitals for the care of persons having tuberculosis. It is proposed that these hospitals shall care for patients in advanced stages of the disease. Experience has proved that while persons with the disease in the early or curable form are willing to remain at the State hospitals, those suffering from an advanced form prefer, as is natural, to be near home and friends, and can only be adequately reached and provided for in local institutions.

3. At the same time another law was passed requiring the State to assist these cities and towns in the maintenance of their hospitals by paying them $5.00 per week per patient, provided such patients are indigent and have tuberculosis germs in their sputum.

4. To complete this plan a law was passed which requires cities and towns of 10,000 inhabitants or over to maintain tuberculosis dispensaries for the discovery, treatment, and supervision of needy persons afflicted with tuberculosis.

WHOSE JOB IS IT TO PROVIDE FOR THE TUBERCULAR?

This program, if carried out, will undoubtedly provide for most of those sufferers from the disease who need care. It means the expenditure of large sums of money, and this in turn means appropriations, raised by taxation; for the cost of maintenance of State, and particularly municipal tuberculosis work, is rapidly increasing.

A bulletin issued recently by the National Association for the Study and Prevention of Tuberculosis shows that nearly $20,000,000 was spent last year in the treatment and prevention of tuberculosis in the United States. This fact clearly indicates that the duty of caring for the tubercular is too great a one for private enterprise, and should therefore be assumed by the State and the municipalities, and paid for by taxation. That this policy is gaining headway is shown in this same bulletin which states that 69.3 per cent. of the above sum of $20,000,000 was derived from public funds, either federal, state, county, or municipal, as against a record of 53.5 per cent. in 1909.

THE STATE'S EQUIPMENT.

Massachusetts maintains at public expense:

1. Four State sanatoria under the Trustees of Hospitals for Consumptives.

2. A hospital for indigent men and one for

indigent women at the State Infirmary, Tewksbury.

3. Thirteen municipal hospitals.
4. Fifteen municipal dispensaries.
5. A prison hospital for tubercular prisoners.
6. And special provision for the tubercular insane at twelve asylums.

PRIVATE INSTITUTIONS.

This State program, however, does not mean that there is no place for the private institution. While a large majority of persons afflicted with tuberculosis are poor or of very moderate means, often with others dependent upon them, there are, of course, many who are amply able to pay for the care and treatment received. For this type of case the private institution is the proper place. There are several hospitals and sanatoria specially endowed for this purpose, and excellent institutions already well established, that should by all means be continued and supported.

THE FIELD FOR THE ANTI-TUBERCULOSIS ASSOCIATION.

In view of the above facts what work remains for an Anti-Tuberculosis Association? It is evident that it:—

1. Should not *permanently* maintain a hospital.
2. Should not *permanently* maintain a dispensary.
3. Shoud not *permanently* maintain a visiting nurse or nurses.

It seems to me, however, not only legitimate but very desirable that an Association should carry on experimental work of this sort to demonstrate a need and should then turn it over permanently to the municipality. The longer the Anti-Tuberculosis Association carries on these enterprises the longer the legitmate duty of the municipality is neglected and the proper work of the Association deferred. If it is impossible to induce a municipality to take over a necessary piece of work, I believe that an Anti-Tuberculosis Association should find some other way of passing on the enterprise. If this is not done the energy of the Association is invariably diverted from its own peculiar and important field of work.

THE PROPER WORK FOR AN ANTI-TUBERCULOSIS ASSOCIATION.

An Anti-Tuberculosis Association should, in my estimation, direct its energy along preventive lines of work; that is, in the direction of investigation, education, experiments and legislation.

INVESTIGATION.

Under the head of investigation it can make a study of local conditions, ascertaining the amount of tuberculosis in a given community, determining whether there is proper equipment to provide for it, and proposing a complete program for the suitable handling of the problem.

EDUCATION.

The object of the educational work should be to instruct people how to guard against contracting the disease, to give information about early symptoms, and what to do to protect others from infection. This can be carried out by free lectures in churches, lodges, labor unions, clubs and theatres; also by the distribution at lectures, schools and clubs of literature dealing with preventive measures, health rules, the value of fresh air, and sleeping-out devices. Exhibits of various sorts may be used to advantage but probably the most useful type is the small portable exhibit that can be shown in schoolrooms and churches, and set up in libraries, settlements, clubs, and even in the waiting rooms of hospitals clinics and stations. The newspapers will be found to be a willing and very useful ally in an educational campaign if material is prepared in a newsy form. Too much credit cannot be given the newspapers for all that they have done to assist in the fight against tuberculosis. Nor must it be forgotten that the sale of the Red Cross Christmas Seal has a certain amount of educational value.

EXPERIMENTAL.

As has already been suggested, experimental work, to demonstrate the need of a hospital, a dispensary, a visiting nurse, a day camp or an open air school, may be carried on by an Anti-Tuberculosis Association to the very great advantage of a community. When a real need of this sort is pointed out in a practical way to a progressive city or town, the public authorities are not slow in taking over and establishing the work on a permanent basis.

LEGISLATION.

Interest in legislation is an important function of an Anti-Tuberculosis Association. If the Association is not near the State Capital it is possible for it to be kept informed of the activities at the State House by some organization that is in close touch with the legislative machinery. Such an organization we have had to a certain degree in the Boston Association, and now with the formation of a Massachusetts Anti-Tuberculosis League we hope that distant Associations may be kept even more closely informed about legislation.

After being apprised of what is before the legislature an active Association may do good work by carefully studying the measures, applying them in theory to its own community, and then bringing pressure to bear on the local legislative representative to aid in enacting or defeating them. If it is possible to unite all the Associations for or against a given measure the pressure will be very effective.

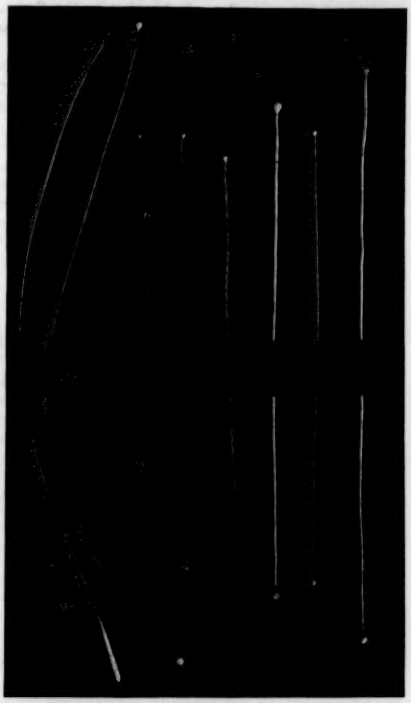
An Anti-Tuberculosis Association can be even more effective by insisting on the enforcement of local or municipal laws, such, for instance, as those requiring physicians to register all cases of tuberculosis, obliging cities to build and maintain tuberculosis hospitals and dispensaries, and forbidding spitting in public places. It is also possible for an Association to do good work along the line of urging ample appropriations for the maintenance of municipal hospitals, dispensaries, nurses, open air schools and the Health Department.

COÖPERATION.

One of the most important things for an Association to cultivate is hearty coöperation with the health authorities, relief agencies, and the various civic bodies. It should always bear in mind that each of these agencies is necessarily looking at the tuberculosis problem from a different point of view, which, while it may not coincide with the point of view of the Association, is nevertheless worthy of the most thoughtful consideration. Toleration is a valuable characteristic and the Association that possessess it will find it comparatively easy to coöperate with others.

New Instruments.

HOME-MADE PROBES.



By Ernest Boyen Young, M.D., Boston,

Junior Visiting Physician for Diseases of Women, Boston City Hospital; Assistant in Gynecology, Harvard Medical School.

Probes are always becoming lost or mislaid, and it is often impossible to procure one of suitable size, length or pliability for special explorations, or in some emergency.

If of a size pliable enough to follow a delicate sinus, the tips are apt to be so small as to engage in any slight irregularity of the passage, and so mislead as to its extent. Furthermore, the material is often so stiff that the probe refuses to follow the tortuous course in friable tissue, and a false passage is the result.

In an emergency a very serviceable probe for small sinuses may be made by tipping a strand of silkworm gut with a drop of paraffin, or by wrapping one end with a wisp of cotton and then dipping one or twice in collodion. When paraffin is used, the end of the gut should be scorched in the flame, which roughens it and makes the paraffin bead secure. Metal probes are naturally more satisfactory, and the writer having found it necessary, in several cases, to employ probes of greater length and flexibility than could be bought, has manufactured them for his own use by a method so simple, that it may be generally useful. In the making, it is possible to vary the size of the beaded tip, according to the caliber of the sinus, so that a very flexible fine probe may be armed with a tip nearly as large as those on the heavy probes sold by the instrument makers, thus providing a flexible probe and at the same time minimizing the danger of the tip engaging or creating a false passage.

1. Silk worm gut tipped with cotton.
2. Same tipped with paraffin.
3. Silver wire with borax bead.
4. Copper wire probe.
5 and 6. Silver wire.

Silver or copper wires of suitable size, are most useful although silver is the better; as the smaller silver wires are easily fused in the common alcohol flame, while larger copper wire always requires the flame of a Bunsen burner. The copper wire also oxidizes and may become rough, while the silver wire comes from the flame bright and ready for use. However, any roughness is easily removed by a piece of fine emery paper, sand paper, or a whetstone, while the roughness of the copper may be obviated by dipping the hot wire in

powdered borax, and again heating in the flame. The borax bead of the chemical laboratory also makes an excellent tip.

Under all circumstances, a Bunsen flame is preferable, as the greater heat gives a smoother bead, but for smaller wire the alcohol flame is sufficient.

Larger probes may be made by twisting together strands of smaller wire, and then forming a bead on one extremity. A loop may also be left on the folded end for the insertion of a strand of silk or other material which it may be desired to introduce into the sinus, or as a guide to indicate the direction of the passage.

Probes made in this manner are also useful in "stirring up" indolent granulations; the twists of the wire acting as a mild curet when pushed back and forth.

The wire should be held upright in the flame until a sufficient bead has collected. A few trials enable one to estimate the size of bead which a given wire will hold, as if allowed to become too large, the melted metal will drop from the wire.

The photograph shows various probes made by the methods described.

Reports of Societies.

THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Meeting of Wednesday, March 4, 1914 at 8 P. M. The President, Dr. James C. Wilson, in the chair.

THREE CASES OF WIRING WITH ELECTROLYSIS FOR AORTIC ANEURYSM. ONE HERETOFORE IN PART REPORTED.

DR. H. A. HARE: Three additional cases of wiring with electrolysis for aneurysm of the thoracic aorta are reported and a patient exhibited illustrating the beneficial effects of this procedure more than four years after the first operation and more than two years after his second wiring which was resorted to because he had a return of very severe pain and a marked bulging near the site of the original sac. The great gain is arrest of the lesion and relief of pain.

To my conclusions in an article published by me in the *Journal of the American Medical Association* of April 13, 1912, I would now add that after having performed this operation twenty-five times I can see no reason for changing the views then expressed. I desire, however, to emphasize once more the fact that only especially prepared wire can be used and that silver wire, because it does not coil, is an unsuitable agent.

DISCUSSION.

DR. GEORGE W. NORRIS: I should like to ask Dr. Hare whether the wire introduced into an aneurysm is ever absorbed? I have an impression that in one case of which I have knowledge no wire was found at autopsy.

DR. THOMAS MCCRAE: I agree with Dr. Hare regarding the absence of danger in wiring, if properly done. Regarding the curious course taken by the wire, I have a specimen in which two loops passed through the aortic orifice and down to the lower end of the ventricle. I have seen one case of anatomical cure of abdominal aneurysm after wiring. The patient died from a second aneurysm which was also wired but without the result of the first occasion. I would ask Dr. Hare whether he has any theory upon the relief of pain by the wiring and electrolysis. The question is certainly not one of coagulation.

DR. JAMES TYSON: On March 27, 1911, I presented to the Section on Medicine of the College an aneurysm which had been twice wired in my wards at the University Hospital, wherein, too, one piece of wire had passed through the aortic orifice down into the apex of the ventricle by two loops.

DR. ROBERT N. WILLSON, JR.: Dr. Hare has encouraged me to mention the unfavorable results of a series of wirings done by us at the Philadelphia Hospital. Of six large aneurysmal sacs four were thoracic; two, abdominal. Five of the patients died within three days after wiring. In all cases the procedure was carried out practically as outlined by Dr. Hare. All showed marked relief from pain immediately following operation. One of the patients went back to work and lived for several months. Not one was benefited permanently. While there was immediate relief from pain, almost without exception, the wiring seemed active in hastening the end. During fourteen years I have seen many times for a colleague a patient with a large slowly growing aneurysm under the upper piece of the sternum, and who during this entire time has been living with reasonable comfort.

DR. HARE, closing: Answering the inquiry whether or not the wire is at times absorbed I would say that it is. I have known of one other case already reported in which at autopsy no wire could be found. I do not know whether, finding a tiny point of the wire protruding, the man had for amusement, pulled it out; or, it had undergone some process of absorption. I am inclined to thing that in some cases the wire may have been partly destroyed by the electrolytic process, particularly, if by any mishap, the negative instead of the positive pole were used. The most notable effect in my series of 25 cases of wiring is the relief of pain. The wire used must have temper so that if handled it will spring into the air. I do not see how coagulation can fail to occur if there has been no mistake in the use of the poles. I attribute the relief from pain to the sedative influence of the galvanic current (although I have not much confidence in electro-therapeutics), and to the removal of the strain upon the sac by the clotting. In cases unimproved or in which there is recurrence of pain it is often found that there is more than one aneurysm. The question at issue is whether we shall operate, or allow a man to live in pain. Of course there must be care in the selection of cases. In two cases seen within the last two months operation would have been unjustifiable. In one the sac was filled with a laminated clot. In the other case there was a history of pain and bulging in the third inter-

space to the right. There was present a small expansile mass. There was so much breath sound around the growth that I questioned whether insertion of the needle was possible without puncture of the lung. On the other hand, in some of the more desperate cases, the aneurysmal sac has been black and blue. In one such case the patient was wired in May and later was wired in two places at one sitting, and died from rupture of another sac than the one wired.

THE UNDERLYING FACTORS IN THE SPREAD OF TUBERCULOSIS.

DR. ALBERT PHILIP FRANCINE: In placing the responsibility for the spread of infection we must in the last analysis begin with the individual. The first remedial step is education among the poor and ignorant; the second, improvement of physical conditions of living. Next in importance in this relation is the subject of conditions of labor. The problem of tuberculosis is in a large sense a social and economic one. It is not alone strictly anti-tuberculosis measures which may be confidently looked to for results, but to all the associated movements for the public welfare in health, morals and conditions. Two great medical factors in the communicability of tuberculosis stand out *i. e.*, source of infection and age of infection. The great source of the infection lies in the carelessness of the individual consumptive, and childhood is the age at which infection occurs. Healthy adults have a very considerable resistance or immunity to tuberculosis, but in proportion to bad environment is this immunity impaired. Infection in childhood, as a rule, lies dormant until adult life. It is largely children infected by contact in their homes who furnish later the ever on-comming crop of consumptives. Infection may also be due to tuberculous milk and meat, and the direct transmission of the tubercle bacillus may take place from mother to fetus by placental circulation. Authoritative opinions differ upon the cause of the decreased death rate from tuberculosis in urban populations. Newsholme concludes that this decrease is due to the institutional treatment of the sick of our cities, and particularly the tuberculous sick. Karl Pearson denies the value of our general campaign, and says that the only efficient source of prevention lies in developing communal or race immunity. The maintenance of racial and communal resistance is important and points to the necessity by good food, rest and recreation, airy schools, playgrounds, inspection and supervision for raising this resistance, particularly in childhood and early adult life. When we consider as essentially one the social and economic, and the more strictly medical, conditions, responsible for tuberculosis, the point is brought forcibly upon us that it is by the combination of our anti-tuberculosis campaign and all allied movements toward improvement of health, morals and conditions of the people that we may expect to control this disease. As Folks well says, "If our task is the more difficult because it is bound up with every phase of modern civilization, it is equally true that every substantial advance in other lines assists our cause."

DISCUSSION.

DR. JAMES TYSON: Dr. Francine has well stated the grounds on which is based the spread of tuberculosis. I should like to ask him whether there is any reason to believe that the ascendancy in the struggle against tuberculosis which is being claimed has been at all reversed? My question is prompted in part by a statement in the lay press (from which, however, it is not always safe to quote) that in France the mortality from tuberculosis had doubled in the last twenty-seven years.

DR. FRANCINE, closing: I have to say, Mr. President, in reply to Dr. Tyson's question, that there is not the slightest possible doubt that the figures for the mortality in relation to the incidence of tuberculosis have diminished enormously. There is confusion from the fact that apparently the morbidity is greater because we are reporting all cases today. The information is before the people in a way never reached before and the mortality is certainly diminishing all along the line.

THE INCIDENCE OF FIBRINOUS AND BRONCHOCATARRHAL PNEUMONIA IN THE PHILADELPHIA GENERAL HOSPITAL.

DR. ROBERT N. WILLSON, JR.: Considerable interest and an occasional good natured difference of opinion have existed during the past eighteen months as the result of the determination of one of the medical services in the Philadelphia General Hospital to discriminate sharply between the fibrinous and the bronchocatarrhal types of pneumonia, especially with a view to treating patients suffering from the one condition in cold; and, from the other, in warm fresh air. There should be a clear cut discrimination between the two clinical types of pneumonia. There is a doubt whether there ever has been, or ever will be, a truly asthenic, vitally vigorous, sufferer from bronchocatarrhal pneumonia. Let us keep those patients indoors who are not able to establish a temperature reaction or a considerable leukocytosis as indications of their attempt to outride the storm that has beset them. Wash and warm, and even re-wash, their breathing air a sufficient number of times to render it cleaner and fresher than outdoor air. Send outdoors only such febrile pneumonies as crave the cold and obtain a stimulus and a relief in and from it. Send even these back into the warmth when the crisis occurs, or when, for any reason, they are distressed by the low temperature.

Book Reviews.

The Cancer Problem. A Statistical Study. By C. E. GREEN, F.R.S.E. Third edition. Edinburgh and London: William Green and Sons. 1914.

The first edition of this interesting monograph was reviewed in the issue of the JOURNAL for May 18, 1911 (Vol. clxiv, p. 723). In this third edition, the text has been considerably rewritten and expanded from 90 to 98 pages by the addition of new data, statistics and other material. There have also been added several new plates, figures, maps and diagrams, and a col-

ored frontispiece; but the volume has been unfortunately curtailed by the omission of its excellent index. The plan of the work remains unchanged. The progress of cancer research during the past three years, especially the work of Mr. Erwin Smith on plant cancer, has on the whole tended to confirm the plausibility of Mr. Green's theory. His position remains as yet, of course, quite hypothetical, yet may well some day be deductively and experimentally proved correct.

Infections of the Hand. By ALLEN B. KANAVEL, M.D. Second edition, thoroughly revised. Philadelphia and New York: Lea and Febiger. 1914.

The first edition of this book was reviewed in the issue of the JOURNAL for May 16, 1912 (Vol. clxvi, p. 743). As indicated in its sub-title, it is "a guide to the surgical treatment of acute and chronic suppurative processes in the fingers, hand, and forearm." In this second edition, the author has made certain additions in regard to chronic processes, has introduced a clearer system of cross-references and has inserted *resumés* at the end of several of the chapters. The number of illustrative engravings is increased from 133 to 147. The total number of pages is increased from 447 to 463. The work should retain its position as an authoritative monograph on the important subject of manual infections.

Sanitary Statistics of the Navy for the Years 1909-1910. Rome: Italian Polygraphic Office. 1913.

This belated biennial report of the chief inspector of health to the Italian minister of marine records the health statistics of the navy for 1909 and 10. It follows the system of the preceding report (reviewed in the issue of the JOURNAL for Apr. 11, 1912 (p. 566) with certain changes in the nosologic tables to keep pace with the progress of medical science. It completes a decennium of statistics. In the succeeding decennium, it is purposed to adopt other simplifications and modifications, not so much in the classification of diseases, as in the number and system of columns. As it stands, the volume presents an immense mass of tabulated data, with a small amount of interpretative text, which should be of undoubted value and interest to those concerned in such subjects.

Dental Diseases in Relation to Public Health. By J. SIM WALLACE D.Sc., M.D., L.D.S. London: The Dental Record. 1914.

This volume consists of three communications made by the author at medical meetings. The first, which comprises over three-fourths of the pages, and from which the book takes its title, was an address before the recent Seventeenth International Medical Congress at London. The second deals with "the physiology of oral hygiene," and was the opening of a discussion on dental hygiene in infancy and childhood, before the Royal Sanitary Institute at Exeter. The third, on "children and dental disease," was presented before the British Medical Association. They indicate well the status and problems of popular education in dental and oral hygiene in England, and therefore should be of special interest to those concerned with similar problems in the United States.

Cunningham's Text-Book of Anatomy. Edited by ARTHUR ROBINSON, M.D., F.R.C.S., Ed. professor of anatomy, University of Edinburgh. Fourth edition, enlarged and rewritten. pp. xxv—1596. New York: William Wood and Company. 1913.

This fourth edition of Cunningham's Anatomy has undergone special revision because of the deaths of Professor Cunningham, Professor Birmingham and Professor A. H. Young. The articles which these men have written for previous editions have been revised and in part rewritten by others. In general, however, the book maintains the appearance of the editions which have gone before. The editor has accepted completely the Basle anatomical nomenclature except in certain instances where the new terms have been unsatisfactory. This text-book remains one of the best composite volumes on the subject of general anatomy. The separate sections are written by men of recognized distinction in their various fields, and the occasional overlapping by the various writers is not to be regarded as a detriment except when insofar as it increases somewhat the size of an already ponderous volume. The illustrations are admirable and printed exclusively in the text. We highly commend this edition as we have its predecessors as one of the relatively few standard books of its type. The work of the American publisher is entirely satisfactory.

A Manual of Medical Treatment or *Clinical Therapeutics.* By I. BURNEY YEO, M.D., F.R.C.P. Fifth edition by RAYMOND CRAWFORD, M.A., M.D., Oxon., F.R.C.P., and E. FARQUHAR BUZZARD, M.D., Oxon, F.R.C.P. In two volumes. William Wood and Company. 1913.

The fifth edition of this manual, which comes in two volumes of eight hundred pages, compressed, however, into a convenient size, will appeal to those physicians who wish to look up the conservative treatment of disease. Many complicated prescriptions are included.

THE BOSTON

Medical and Surgical Journal

THURSDAY, APRIL 30, 1914.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States. $6.56 per year for all foreign countries belonging to the Postal Union.*

Papers for publication, and all other communications for the Editorial Department, should be sent to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston. All orders for reprints must be sent in writing to the Editor on or before the day of publication.

The Journal will furnish 100 reprints free, if requested in writing.

All letters containing business communications, or referring to the publication, subscription or advertising department of the Journal, should be addressed to the undersigned.

Remittances should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

THE ANTI-VACCINATION BILL.

OPPOSITION to vaccination arose just as soon as Jenner told the world "duly and efficiently performed it will protect the constitution from subsequent attacks of smallpox as much as that disease itself will. I have never expected that it would do more and it will not, I believe, do less." Cartoonists seized upon the subject in the early days of vaccination, and many sermons were preached against the practice. It is curious that from the beginning most of those who opposed vaccination refused to study its effects at first hand, but based their opinion upon theoretical, sentimental, or religious grounds. Many a detractor wanted to make the fate of vaccination hang upon a single case of smallpox. Jenner never claimed vaccination to be an infallible prevention, and always took care to emphasize the fact that has been demonstrated over and over again during the past hundred years, that vaccination protects against smallpox in the same way that smallpox protects against smallpox. Some people have smallpox two, three, and four times. Jenner mentions, "The lady of Mr. Guinnett, who has had the smallpox five times. . . ."

We now know perfectly well that the effects of vaccination wear off in time, and that persons should be re-vaccinated in order that the protection may be renewed. Persons successfully vaccinated on two occasions are usually immune from smallpox for life. Vaccination and re-vaccination, systematically and generally carried out, confer complete protection to a community or a nation. In other words, while the individual protection is not always perfect, the communal protection is absolute.

Thomas Jefferson, in 1806, wrote to Jenner saying, "Future nations will know by history only that the loathsome smallpox has existed, and by you has been extirpated." This prophecy has not been fulfilled, though eminently possible. Germany has taught the world how to utilize Jenner's great demonstration. On April 8, 1874, Germany passed a general compulsory vaccination and re-vaccination law. This law requires the vaccination of all infants before the expiration of the first year of life, and a second vaccination at the age of twelve. Since this law went into effect there have been no outbreaks of smallpox in Germany; in fact, the disease has practically been abolished from that great nation.

Those who have practical experience with smallpox soon learn that persons who have been well vaccinated do not contract the disease, while those who have not been vaccinated almost invariably do so if exposed. The most convincing demonstration is to visit a smallpox hospital, where doctors, nurses, ward-tenders, and others who come in frequent and intimate contact with many cases of smallpox, never contract the disease.

One of the most convincing demonstrations concerning the efficiency of vaccination was made in Boston on August 16, 1802, when nineteen boys were vaccinated with the cow-pox. On November 9 twelve of them were inoculated with smallpox; nothing followed. A control experiment was made by inoculating two unvaccinated boys with the same smallpox virus; both took the disease. The nineteen children of August 16 were again unsuccessfully inoculated with fresh virus from these two boys. This is one of the most crucial experiments in the history of vaccination, and fully justified the conclusions of the Board of Health—*cow-pox is a complete security against the smallpox.*

The splendid results recently obtained in the Philippines are a modern demonstration of the practical results of vaccination.

Much fuss has been made concerning the dangers of vaccination. The alleged dangers have been greatly magnified. The chief danger lies in the fact that an open wound is produced which is subject to the complications of any wound. Even a pin prick or a razor scratch may result in death. When the aggregate number of acci-

dents resulting from the complications of vaccination are considered, the total is so small that the individual risk may be disregarded. Furthermore, the methods of vaccination have been greatly improved during the past decade, and the quality of the vaccine virus furnished through government inspection and control, in accordance with the law of July 1, 1902, is a safeguard which ensures a pure and potent vaccine virus.

John Ring was an active protagonist of the cause of vaccination, and was accustomed to answer antivaccination arguments with a vigorous pen. On one occasion Jenner wrote to John Ring as follows, "Your satires against the antivaccinationists are keen, but the keenest of all are those which are engraved with the point of your lancet."

THE ALIEN INSANE IN THE CIVIL HOSPITALS OF NEW YORK STATE.

DR. SPENCER L. DAWES of Albany, appointed by Governor Dix special commissioner to make an investigation on this subject, in order to ascertain existing conditions and their causes, and suggest remedies therefor, has submitted to Governor Glynn an elaborate report of his studies. These were based upon: (1) public hearings at the state hospitals for the care of the insane; (2) public hearings in Albany and New York, at which were examined hospital superintendents, representatives of charitable institutions, of steamship companies, and of foreign governments, the chief examiner of the Bureau of Deportation and his assistants, and private citizens; (3) statistics of the nativity and citizenship of every patient in the state hospitals, obtained from a special census taken September 30, 1912.

The investigation covered a large number of topics, among which were, provision for cost and maintenance of the insane in the state, increase of insane patients in the state hospitals compared with increase in general population, nativity and parentage of the insane in New York State and the United States, time of aliens in this country before admission to state hospitals, cost of caring for the alien insane, eugenic effects, and attitudes of other states. As to the matter of eugenics, it is stated that the long-standing belief in the popular mind of the association of insanity with heredity has been confirmed by modern investigation, so far, at least, as to establish the point that heredity is by far the most important single factor in the causation of certain forms of mental disease. To ancestors afflicted with feeble-mindedness, dementia precox, and other mental disorders, numerous mentally defective or mentally diseased descendants have been traced in many of the families which have been investigated, while in a few of the cases examined, where one party to the marriage was normal (and presumably of normal ancestry), the other being insane, some normal children resulted. The result of investigations into heredity down to the present time entirely justifies the statement that it is highly undesirable that the feeble-minded, epileptics and those with certain types of insanity should have children. The opinion is therefore expressed that mental defectives, the insane, and those particularly likely to become insane, who are so undesirable as parents of future generations of Americans, should be excluded, as far as possible, from entry into the state and country. If, however, they have been admitted, but have not become citizens, they should be returned to the homes from which they came.

In the report is included a series of recommendations, first, for the State of New York, and, second, for action by the United States Government. Under the first heading it is advised that since at present the only authority under which an insane alien can be debarred from entering this country is the federal law, which can be enforced only by federal officers, the state, through its executive or legislature, should urge upon congress the necessity of providing sufficient appropriations for the efficient enforcement of the Immigration Act and of enacting needed amendments to this. The part of the state in effecting deportation of insane and mentally defective aliens consists in reporting such cases to the federal immigration authorities, furnishing information for the verification of their landing, and certifying to the conditions found and their origin from causes which existed prior to landing. This work, so far as it relates to the insane, should be performed more efficiently each year by the Bureau of Deportation, with the coöperation of the State Hospital Commission and the superintendents of state hospitals, provided that adequate funds are provided for the purpose. For the past three years the number of aliens repatriated and of non-residents returned from the

state has each exceeded the number of aliens deported by the federal authorities. As repatriation at present depends upon the consent of the steamship companies, it is highly desirable that the rights of the state in this matter should be protected without further delay by amendments to the federal and state laws. Better arrangements should be made with the proper authorities of foreign governments for the reception of insane aliens repatriated by the state. Existing facilities for statistical research should be extended and used to the fullest extent for the study of the whole question of the alien insane, along the lines of this inquiry.

The recommendations for action by the federal government are given in two divisions: (*a*) under existing laws, (*b*) new legislation recommended. In the first, as to the exclusion of insane and mentally defective immigrants at the time of their arrival, it is stated that there is need for the employment at the ports of entry of more trained alienists, that, as far as possible, physicians skilled in the detection of mental diseases and defects should be selected from the candidates for admission to the Public Health Service, and that, in order to insure a greater number of alienists, physicians in this service should be detailed for training at hospitals for the insane. All that is required for putting these recommendations into effect is the necessary appropriations, and unless the things are done, much of the legislation recommended will be ineffective. There is also needed the employment and careful training of a sufficient number of interpreters for this part of the medical examination.

A number of recommendations are then made in regard to deportation by federal warrant of insane aliens who become public charges from prior causes or are found in the state in violation of law. In the division of new legislation recommended the following points are taken up: 1. Exclusion of insane and mentally defective immigrants at the time of their arrival or before embarkation. 2. Deportation by federal warrant of insane aliens who become public charges from causes existing prior to landing or are found in the state in violation of the Immigration Act. 3. Repatriation of aliens at expense of state or friends, and with consent of aliens themselves. 4. Appropriations. 5. The proper method of returning the alien insane to their homes. It is impossible to detail the various recommendations here, but the following under the first point may be mentioned as worthy of special attention: It is urged that the Immigration Act should exclude immigrants with chronic alcoholism and those with psychopathic inferiority (many of these cases, though detected at the ports of entry, pass the inspecting officers, as the present law does not forbid their admission); that the act should provide that each immigrant examined receive at the port of entry a certificate that no mental or physical diseases or defects were found, or that those found had been set forth therein; that it should provide for the imposition upon transportation companies of a fine of not less than $200 for bringing to this country any alien whose insanity, mental defect, chronic alcoholism, or constitutional psychopathic inferiority could have been detected by a competent medical examination prior to embarkation; and that it should provide for a special study of the methods employed in the detection of mental diseases and defects among immigrants, the changes desirable, etc., by a board of medical experts, including officers of the Public Health Service and physicians in civil life who are especially familiar with the subjects involved.

PREPARATIONS FOR MILITARY AND NAVAL SURGERY IN MEXICO.

With the final and actual outbreak of hostilities between the Mexicans and the United States troops, the possibilities of active military surgery and nursing in this country become immediate and imminent. The medical corps of both the Army and the Navy are in a state of admirable and prepared efficiency. On April 22, Surgeon-General Braisted of the Navy published the following plans for caring for the naval sick, wounded, and dead.

"The medical department is actively at work preparing for the care of the sick and injured, not alone of our own, but of the enemy as well, as demanded by the Geneva convention.

"The naval organization for the ships and landing parties is complete in all regards, and steps for the care of the sick and wounded and for sanitation and the preservation of health ashore are being taken in conjunction with the Public Health service and Red Cross organization.

"It is the intention to bring the remains of all naval dead to the United States at the

earliest opportunity, dependent upon the circumstances and location attending the fatalities, and either to forward them to the next of kin or to make final interment in a national cemetery, as may be desired by the families of the deceased. All expenses of the dead will be defrayed by the United States."

On April 22 also Surgeon-General Gorgas of the Army presided at a meeting of the executive committee of the Red Cross, at which a program was arranged for nursing at field hospitals.

Military medicine and camp hygiene have made great progress since, and partly in direct consequence of, the war between the United States and Spain, and our state of preparation should be much better now than it was at the outbreak of that conflict. Particularly the development of antityphoid inoculation has enabled the protection of practically our entire army and navy against one of the most dreaded and fatal of military epidemic diseases. Moreover, the Red Cross stands ready to send at immediate notice 4200 nurses to augment the regular nursing corps, so that the deficiency of nurses, which was so grievous at the beginning of the Spanish War, should not now occur.

Probably no class in the community regrets the necessity of war more than do physicians and nurses. Yet, whether from civil or from military life, probably no class will make a readier response to the demand upon them for service at the front, for working on the firing-line is with them a daily professional habit.

AN IMPORTANT TRIAL ON ANIMAL EXPERIMENTATION.

A TRIAL has recently been held in Philadelphia, whose decision will have an important bearing, as precedent, on freedom or restriction of animal experimentation in this country. The Women's Pennsylvania Society for the Prevention of Cruelty to Animals caused the arrest of Dr. Richard M. Pearce, Dr. Joshua E. Sweet, Dr. Alonzo E. Taylor, and three other members of the medical faculty of the University of Pennsylvania, for alleged cruel treatment of dogs after operations. Much of the evidence brought by the prosecution was of the nature of the absurd accusations usually made by anti-vivisectionists.

In the course of his charge to the jury Judge Bregy said:—

"To indicate a view on the part of physicians that these operations upon the dogs were made for scientific purposes to obtain information for the alleviation of human suffering, I charge you that the law of Pennsylvania does not allow pain and suffering, torment or torture to be inflicted upon dogs for any purpose except the relief of the suffering of the dog itself. They have no right to torture a dog or violate the law as I have read it to you for the purpose of obtaining scientific information. The law says that any person that does a thing as I have read it to you—that is, if a person is guilty of wanton cruel torture of an animal he shall be guilty of a crime."

After being out over 48 hours the jury reported a disagreement and was discharged. It is expected that a new jury will be empanelled. Meantime the prosecution, encouraged, has announced its intention to secure new warrants for the arrest of other prominent physicians and invesigators, charging them with cruelty in performing surgical operations on animals.

MEDICAL NOTES.

NEW JERSEY STATE BOARD OF HEALTH.—The somewhat belated thirty-sixth annual report of the board of health of the state of New Jersey, recently published, records the activities of that body for the year ended Oct. 31, 1912, together with the report of the bureau of vital statistics for the same period. The report of the secretary, Dr. Bruce S. Keator, is followed by those of the divisions of medical and sanitary inspection, creameries and dairies, state laboratory of hygiene, food and drugs, sewerage and water-supplies. The report of the bureau of vital statistics consists almost entirely of tabulated data.

THE AMERICAN SOCIETY FOR PHYSICIANS' STUDY TRAVELS.—The American Society for Physicians' Study Travels will make its first tour immediately after the close of the next meeting of the American Medical Association, starting from Atlantic City June 26. The complete itinerary can be obtained upon application to the secretary, Dr. Albert Bernheim, 1225 Spruce Street, Philadelphia, and it will be found to promise an interesting, pleasant and profitable

outing to all participants. The objects of the newly-formed organization are in the main to afford an opportunity to make the best use of one's vacation, time and money, in seeing cities and health resorts, and gaining practical knowledge of their institutions—medical, historical, and municipal—as well as to attend clinics, demonstrations, lectures, illustrated with lantern slides, and public addresses.

In addition, however, many sight-seeing trips have been arranged for, and the path of the Society lies by rail and water through a section of this country and Canada abounding in picturesque, sylvan, and grand scenes, so that the tourist, whatever his individual taste, will enjoy the advantages of healthful recreation en route. It is believed that American physicians and their wives will appreciate the benefits of these tours, which have become so popular, both in Germany and in France, where they are undertaken even more than once annually.

Early bookings, through the secretary, are urged, in order that satisfactory accommodations can be secured for all who desire to participate.

Jubilee of Melbourne University Medical School.—The medical school of the University of Melbourne, the oldest medical school in Australia, will during the remainder of this current week, celebrate the jubilee of its foundation. During the fifty years of its existence it has already graduated about 1100 practitioners, and now has an attendance of 380 students.

"The Melbourne School has from the first insisted on a five years' course, and its degrees have been registrable in the United Kingdom since 1890. The celebrations will commence on Thursday, April 30, and will last three days. The university is asking the state government to provide funds for the appointment of assistant professors of anatomy, physiology and pathology, the proper staffing of these departments being regarded by the faculty of medicine as the most pressing want of the school. Old graduates are being invited to contribute varying sums annually for five years to a permanent fund, the interest of which will be devoted to the promotion of clinical research in the teaching hospitals of Melbourne. A history of the medical school is being prepared. The jubilee celebrations will include an inaugural ceremony in the Wilson Hall of the university; a series of short addresses on the history, needs and prospects of the school; demonstrations in the laboratories, museums and hospitals; a jubilee dinner, and a theatre party. A portrait of the dean of the faculty, Sir H. B. Allen, is to be painted for presentation to the university."

BOSTON AND NEW ENGLAND.

Milk and Baby Hygiene Association.—The recently published fifth annual report of the Boston Milk and Baby Hygiene Association records the work of that organization during the past year. In this period the number of milk stations was increased from 9 to 12. The number of babies cared for in 1913 increased 13% over 1912; 3421 babies made 13,754 weekly visits to the milk station conferences; and 41,945 visits were made by nurses to babies in their homes. Of the babies cared for by the Association, one-half were breast-fed.

Prevention of Milk-Borne Epidemics.—The Massachusetts State Board of Health has recently sent to every practitioner in the Commonwealth a circular letter calling attention to a recent vote of the Board,

"That beginning March 1, 1914, it shall be the duty of the officers in charge of any city or state institution, charitable institution, public or private hospital, dispensary or lying-in hospital, or any local board of health or any physician in any city or town to give immediate notice (preferably by telephone or telegram, 'collect') to the State Board of Health, Room 145, State House, Boston, Mass., in every case coming to their notice in which typhoid fever, diphtheria or scarlet fever has occurred in the household of any person engaged in the production, transportation or distribution of milk for public sale; and in every case coming to their notice in which typhoid fever, diphtheria or scarlet fever has been due, or presumably has been due, to the consumption of milk infected with material derived from persons infected with said diseases."

The purpose of this regulation is to aid the Board in its effort to prevent epidemics due to the contamination of milk supplies.

Massachusetts Homeopathic Medical Society.—The seventy-fourth annual meeting of the Massachusetts Homeopathic Medical Society, held recently in Boston, was attended by about 200 members. At the closing session, the following officers were elected for the ensuing year: President, Dr. T. E. Chandler of Boston; first vice-president, Dr. Amanda C. Bray of Worcester; second vice-president, Dr. Harry J. Lee of Boston; recording secretary, Dr. E. S. Calderwood of Roxbury; corresponding secre-

tary, Dr. Benjamin T. Loring of Boston; treasurer, Thomas M. Strong of Boston; and chairman of the board of censors, Dr. George R. Southwick of Boston.

HOSPITAL BEQUESTS.—The will of the late Susan H. Leeds, of Boston, which was filed recently in the Suffolk registry of probate, contains a bequest of $500 to the Boston Floating Hospital. It also provides that one-half of the ultimate residue of the estate shall be given to the city of Boston for use in its department for consumptives.

The will of the late Sarah S. Pierce, of Lynn, Mass., which was filed on April 21 in the Essex County registry of probate, provides that on the death of her husband $1000 shall be given to the Lynn Hospital, to be known as the Pierce Fund.

CASES OF INFECTIOUS DISEASES reported to the Boston Board of Health for the week ending March 21, 1914: Diphtheria, 39; scarlatina, 127, of which 13 were non-residents; typhoid fever, 2; measles, 78, of which 1 was non-resident; tuberculosis, 42, of which 3 were non-residents.

The death-rate of the reported deaths for the week was 21.32.

NEW YORK.

VISITING OF INFECTIOUS DISEASES.—On April 1 the City Health Department inaugurated the practice of having all cases of measles, scarlet fever, and diphtheria discharged from the hospitals of the department visited at once by the district nurse of the Bureau of Infectious Diseases, to determine the condition of the patient (as to infectivity, etc.), and the home condition of the family. Advice is given as to the care of the convalescent patient and if necessary the family is referred to the proper charitable organization for financial and other assistance. At least one additional visit is made after the expiration of the incubation period of the disease, to ascertain if any secondary cases have developed. It is announced that it is the intention of the Commissioner of Health to eventually give to this work the full force of hospital social service visiting in the complete sense of the term, although this will, naturally, necessitate a large staff of district nurses. The establishment of a special convalescent home for suitable cases is one of the possibilities hoped for.

PROVISION FOR PERTUSSIS.—At a meeting of the Section on Pediatrics of the New York Academy of Medicine, held on April 9, at which whooping-cough was the topic of the papers and discussions, a resolution was adopted providing for the appointment of a committee to urge upon the Health Department, in view of the present large direct and indirect mortality from the disease, the necessity of making more ample provision for dealing with it.

REORGANIZATION AT PRESBYTERIAN HOSPITAL.—It is announced that the managers of the Presbyterian Hospital, New York, have so reorganized the clinical and scientific work as more closely to coördinate it with the instruction in the College of Physicians and Surgeons, Columbia University. Dr. Theodore C. Janeway, Bard professor of the practise of medicine, has been appointed medical director; Dr. George E. Brewer, professor of surgery, surgical director; and Dr. William G. MacCallum, professor of pathology, pathologist. All these appointees will have continuous service and single responsibility.

ALIEN INSANE IN NEW YORK.—The recently published report of Dr. Spencer L. Dawes, special commissioner on the alien insane in the civil hospitals of New York State, presents a large amount of tabulated statistics, with discussion thereof, and recommendations for both state and nation in dealing with the problem. These recommendations fall under three headings: first, the exclusion of insane and mentally defective immigrants at the time of their arrival; second, the deportation of insane aliens by federal warrant; third, the repatriation of aliens with their consent at the expense of the state or of friends.

GLANDERS.—The latest number of the *Monthly Bulletin* of the City Health Department is largely devoted to the subject of glanders in the horse and in man, which, it declares, is one of those diseases, like typhoid fever and Asiatic cholera, that ought not to exist in our modern civilization. In the Borough of Manhattan in 1913 there were discovered 589 glandered animals among approximately 65,000 horses, or about 9 out of every 1000. The disease is found to be most frequently transmitted through blacksmith shops and public drinking troughs. The returns in the Bureau of Records show that in the city of New York there were in 1909 three deaths from human glanders; in 1910, four; in 1911, three; in 1912, five; and in 1913, one.

Boylan Anti-Narcotic Bill. — Governor Glynn has signed the Boylan anti-narcotic bill, recently passed by the legislature. One of the features of this is that physicians, druggists, dentists and veterinarians are required to obtain from the Health Department blanks, bound in book form, in which to keep duplicate records of the purchase of narcotic drugs and of the manner of their disposal. The governor has also signed the bill amending the State charities law in relation to the commitment of the feeble-minded, and another bill providing for a commission to investigate the custody, treatment and training of the mentally deficient, and submit a full report for action by the next legislature. The law now made effective authorizes any judge of a court of record to determine the mental condition of any person alleged to be feeble-minded, and, after hearing the evidence, to commit, at his discretion, the person to a public institution. It is specified that every application for commitment must be accompanied by the certificate of two physicians to the effect that in their opinion the person named is mentally deficient.

1. Henderson gives concrete examples of an interesting series of experiments on respiration in the normal human subject. No conclusions are drawn. The paper is a statement of effects.

2. The authors in a careful and well tabulated review find that athletic training leads at first to physiologic hypertrophy of the heart, but when prolonged and weakened by severe athletic contests it usually leads to hypertrophy plus dilatation of a variable degree, frequently marked by valvular insufficiency. Functionally, the hypertrophied heart, even when dilated and giving distinct evidence of valvular insufficiency, may prove more fitted to carry the man through a severe athletic contest than a normal heart.

3. Mitchell finds that many pains for which we are otherwise unable to find a proper cause are due to a temporary ischemia or anemia of the part, which, under proper treatment with agents causing vasodilation, are readily cured.

5. Haas successfully transplanted free bone between resected areas in the phalanges and obtained satisfactory union and functional results.

10. Shalet believes that every case of tuberculosis should be treated with tuberculin. Of the pulmonary type there is no way of telling beforehand what cases will be benefited the most, but all should be given a trial. In his series 25% showed distinct improvement or were apparently cured; 15% were made worse. The effect of tuberculin on localized visible tuberculosis, such as fistulae in ano, glands of the neck, etc., is marked, and in the case of glands of the neck by far the treatment of choice. [E. H. R.]

2. Bloodgood's article is the type of exposition which should be in the hands of every practitioner throughout the country. He divides his cases into three groups: 1a, in which local excision of the growth only was done, after five years the percentage or probability of cure was found to be 63%. Group 1b, glands negative, shows 95% cures, and group 1b, glands positive, shows only 50% cures. He believes that the operative removal of the glands is always indicated, and the percentage of cures depends largely on early operation. The article is well illustrated and the figures should be studied in detail.

3. Paterson finds that after gastrojejunostomy, which he believes to be a physiological operation and not a purely mechanical one, the total gastric chlorides are reduced on the average 30%. He also thinks that we might safely return to the anterior operation without harm. Occlusion of the pylorus after the above operation is an unnecessary complication and based on erroneous pathology. Gastrojejunostomy is preferable to excision of ulcer near the pylorus or in the body of the stomach.

4. Crile believes that in the type of case which has recurrent cyclic disturbances or repetition of previous symptoms after cholecystostomy, that cholecystectomy is the operation of choice, the latter showing less morbidity. The clinical end results of cholecystectomy are good, while in unsuitable cases cholecystostomy is followed by recurrent cholecystitis. If acute infection be present then in most cases cholecystostomy should be done first, to be followed later by cholecystectomy.

7. Kelly and Dumm describe the progressive incontinence of urine occurring in middle aged women without history of any trauma except childbirth, and the numerous methods, both medical and surgical, for its control, and describe and illustrate a simple operative procedure, which can be done under local anesthesia. Of twenty cases done sixteen have been cured. The paper is a valuable one.

10. This paper is an extremely interesting and practical piece of work on a so far little explained subject. The authors conclude from extensive evidence furnished from the literature and experiment that an extensive network of lymph-vessels and channels exists in the mucosa and submucosa, in the external coats of the bladder and the ureters and in the entire structure of the kidney. This network in the bladder anastomoses freely with the lymphatics of the bladder at the one end, and with the lymph apparatus of the kidney at the other end. They believe that an ascending infection travels through this lymphatic system, not through the blood vessels of the ureter nor through the lumen of the ureter. They give ample reason why the blood vessels and the ureter can be excluded as avenues of ascending infection. The paper is well worth careful reading and is suggestive in the way of treatment.

11. The author makes the sweeping but more or less convincing statement that there is no organ or tissue in the whole body that may not be at the mercy of infection that gains entrance through or around the teeth.

14. Johnston suggests that epileptic seizures may be due to the deprivation of the system of the products of the pituitary gland and suggests feeding these patients on this substance, with gradual withdrawal of bromides.

15. Codman's article on the product of a hospital is of very practical importance. [E. H. R.]

THE LANCET.

MARCH 28, 1914.

5. TRESIDDER, A. G. *A Case of Malarial Coma Lasting Forty-six Hours; Recovery.*

1. In an article illustrated with numerous plates, Whitehouse in the first part of the Hunterian Lecture discusses uterine hemorrhage and its physiology and pathology. He has done numerous experiments on the coagulation time of blood at menstrual periods and of the menstrual blood itself as to the presence of antithrombin in this and in the endometrium. He describes numerous other experiments along this line.

3. Neve reviews his results on 850 operations for hemorrhoids.

4. Cook believes that excessively soft water is a causative factor of importance in producing dental caries in children and should be borne in mind along with other causes. [J. B. H.]

BRITISH MEDICAL JOURNAL.

MARCH 28, 1914.

1. *MACWILLIAM, J. A., AND MELVIN, G. S. *Systolic and Diastolic Blood Pressure Estimation, with Special Reference to the Auditory Method.*
2. *MURRAY, J. R. *Systolic and Diastolic Blood Pressures in Aortic Regurgitation.*
3. ROBINSON, H. B. *Three Cases of Pancreatic Cyst.*
4. BEVERS, E. C. *A Renal Cyst Causing Chronic Intestinal Obstruction.*
5. *RAEBURN, J. A. *Subcutaneous Injections of Emetine in Pulmonary Tuberculosis.*
6. ROSEBRUGH, A. M. *An Economical Treatment of Inebriates.*
7. *SHUFFLEBOTHAM, F. *The Milroy Lectures on the Hygienic Aspect of the Coal-mining Industry in the United Kingdom. Lecture IV.*

1. The writers discuss the significance of diastolic blood pressure as compared to the variable systolic. They describe the auditory method, its application, the apparatus used and the estimation of systolic and diastolic pressures by this method. They believe that its simplicity, care and rapidity are points in its favor. In brief, this method consists in using a tambour, connected with the ears as a stethoscope, placed underneath the pressure cuff and over the brachial artery above the bend of the arm. Pressure is applied so as to shut off the pulse entirely, then as it decreases a sharp thud is heard at the exact time that the blood first goes through the artery.

2. Murray, using the auditory method, discusses blood pressure in aortic regurgitation under varying conditions.

5. Raeburn, endorsing the results of Flandin and Joltrain as to the value of emetine in hemorrhage in consumption, also found it of great value in cases of bronchitis alone, in cases presumably tuberculous but without bacilli in the sputum, but of little value in open cases of pulmonary tuberculosis with bacilli present.

7. Shufflebotham believes that miners' nystagmus is due to 4 causes: (1) defective illumination in the mines, (2) the peculiar cramped position of the miners, (3) refractive errors frequent among the miners themselves, and (4) the frequent injuries which miners sustain to themselves and to their eyes. He discusses treatment of the eyes and of the general condition and preventive measures in detail.

15. CORBEN, C. *Schlatter's Disease.*

1. This is a general clinical article reviewing the functions of various ductless glands, although presenting nothing new.

2. Rolleston in a scholarly way, goes over the subject of chronic splenic anemia and its separation from Banti's disease and other conditions. Very little is known in regard to its pathogeny except that as splenectomy cures the disease, the spleen must in some way be responsible, and that there is *not* any active haemic infection or intoxication at work; also that splenic inadequacy is not the cause of the anemia. He discusses in detail the ways in which the spleen may cause the anemia. Later on he seems to contradict himself by stating that (*a*) in splenic anemia a chronic infective or toxic process has (*c.f.* above) its headquarters in the spleen, which thereby undergoes fibrotic enlargement; (*b*) that the large spleen mechanically causes gastric hemorrhage and the resulting anemia, and that poisons from the spleen eventually cause cirrhosis of the liver. He describes the clinical picture, blood changes, etc., symptoms, differential diagnosis, etc. There is an elaborate list of references.

3. Tooth, in a long paper, records his study of 497 cases of cerebral tumor which have come under observation and treatment at the National Hospital in London from 1902 to 1911. He first discusses these tumors and operations topographically, those occurring in the forebrain and those in the cerebellum. He describes the urgent signs and symptoms, the nature of the operation, site, sequelae of the first and second stages of such operations and results. The paper is a most valuable contribution to the subject.

4. Edmunds, in a long paper with excellent plates, discusses ectopia of the bladder. He believes that plastic operations to merely reconstruct the bladder are unsatisfactory and that transplantation of the base of the bladder is better than the separate transplantation of the ureters. The wound should be left freely open. [J. B. H.]

MÜNCHENER MEDIZINISCHE WOCHENSCHRIFT.

3. Rach has controlled radiological findings in the lungs of children with tuberculosis by autopsy. He believes that it is possible to differentiate six different anatomical types of the disease by a combination of x-ray and physical findings. These are: (1) Ghon's primary lung focus, where isolated tuberculous foci are found with or without tuberculosis of the bronchial glands. (2) Tuberculosis of the glands, where isolated shadows are seen in the region of the bronchial lymph nodes. (3) Hilus tuberculosis of two forms, (*a*) arising from an intrapulmonic focus and extending along the lung hilus, (*b*) due to extension inwards from a primary infection originating from tuberculosis of the lymph nodes of the hilus. (4) Miliary tuberculosis of the lungs. (5) Tuberculosis of sucklings, characterized by extensive cavity formation. (6) Apical tuberculosis analogous to that found in adults.

7. At present most serologists use alcoholic extracts of normal organs as antigen in the Wassermann reaction. It has been found empirically that lecithin, oleic acid, and cholesterin have certain specific antigenic properties. This has led to attempts to isolate the specific chemical antigen from these various extracts.

Klein and Fränkel have made chemical and serological studies with an alcoholic extract of beef heart. They believe that the most powerful antigenic action was obtained by the combined effect of lecithin with a small amount of an unrecognized soapy substance and free cholesterin. Whether more complicated substances have to do with the reaction will be demonstrated by future studies. [R. F.]

1. Engelhorn and Wintz have made "Placentin" analogous to tuberculin and luetin, to be used for the intracutaneous diagnosis of pregnancy. Its method of preparation is not sufficiently simplified for general use, so Engelhorn and Wintz do not describe it. It is an extract of placenta which is injected intracutaneously according to Pirquet's method. The results are either sharply positive or negative within forty-eight hours, and are most marked thirty-six hours after injection. Among seventy pregnant women, the reaction was positive in every case, as early as the seventh or eighth week after conception, and as late as the tenth month. In fifty-three non-gravid patients the reaction was negative in every case except one, which was that of a six-year-old child. The reaction did not remain positive after the fourth day of the puerperium.

Engelhorn and Wintz conclude that a larger series of cases must be tested before too much is claimed for the specificity of the "Placentin" reaction. They feel justified, however, in publishing these suggestive results.

5. Funk believes that beri-beri is caused by the eating of rice which has been polished free of its "vitamin" bodies, and that pellagra is due to the ingestion of polished maize. He comments upon the frequency and high mortality of pellagra in this country. Between 1907-1912 there were twenty thousand fatal cases.

Funk considers that the prophylaxis and treatment of pellagra is simple. Maize, only, which has been untreated should be eaten, and in any pellagra zone other "vitamin" containing vegetables should be cultivated, or if this is impossible, they should be imported duty free. For treatment, foods should be given in abundance which contain "vitamin" substances, such as uncooked fruit-juice and milk, butter, and for carbohydrates, potatoes. [R. F.]

Miscellany.

EXPERIENCE WITH EUGENICS IN PHILADELPHIA.

The following item from a recent issue of the Philadelphia *Bulletin* is another evidence of the impracticability of so-called eugenic marriage laws, at least in their present form. The failure of the experiment in Philadelphia is analogous

to that in Detroit, Mich., and for a fundamental reason well stated in the last paragraph of the quotation:

"After an eight months' trial, Chief Clerk Ferguson of the local marriage license bureau virtually admits that the amended marriage license law partly based on 'eugenics' is a failure, when he says that only one case has arisen in Pennsylvania since the act became effective, where an applicant was refused a permit for disabilities classified under it. He points out that the weakness of the statute in practice lies in the fact that the clerks have no right to deny a license so long as the applicants give technically 'satisfactory' answers to the prescribed questions concerning health and physical condition, even though the replies may be palpably untrue.

"In other words, about the only result accomplished by the change in the old laws has been to impose increased burdens on the clerks and to subject all applicants to annoying and embarrassing personal questions, without preventing the unfit from entering matrimony. It is inconceivable that every one of the thousands of persons who have applied for licenses in the State since the first of last August should have been free of the impediments recited by the law either in the matter of bodily soundness or in ability 'to support a family' as the clause is worded, if the statistics compiled by the sociologists and eugenists are right in their conclusions regarding the dissemination of disease and other forms of wretchedness.

"The ineffectiveness of the Pennsylvania law is not remarkable, however, for the same result has been reported in other States where even more drastic legislation has been attempted. It only goes to prove what the eugenic theorists entirely overlook, that when couples make up their minds they are suited to each other no mere law is going to prevent them from mating."

INFANT MORTALITY IN NEW ZEALAND.

A PAMPHLET on methods of reducing infant mortality, as illustrated in the work of the New Zealand Society for the Health of Women and Children, has recently been published by the children's bureau of the United States department of labor. In her introduction to this pamphlet, Miss Julia C. Lathrop, chief of the bureau, writes as follows:—

"The infant mortality rate of New Zealand has been for some time recognized as the lowest of any country in the world, and it is stated that recent further reductions are due in large measure to the activity of this society. As an example of its value, the consul general states that the work of the society has reduced infant mortality in Dunedin, a residential city of about 60,000 inhabitants, 50% during five years, from 1907 to 1912. Because of the absence of adequate birth and death registration in the United States, the infant death-rate of this country as a whole is unknown, but estimates tend to show that it is at least twice the rate of New Zealand, which the registrar general of that country reported in 1912 to be 51 per 1,000. New Zealand, like certain of our states, is a young and vigorous country with a scattered population and with no large cities, and there is every reason to believe that similar volunteer effort in this country would produce similar results. In view of the marked and growing interest in the preservation of infant health in the smaller cities and rural communities of the United States, I believe that the account of the methods of the New Zealand society is especially timely. It will be seen that public interest is strongly enlisted in its efforts. Seventy volunteer committees in as many districts maintain the educational and nursing work in conjunction with the central office, and the government itself assists in various ways. The detailed statement which follows is not offered for the purpose of urging exact reproduction of the New Zealand organization, but rather to stimulate interest in working out whatever methods are practicable locally for securing the same results."

The following points are summarized as conclusions from this study of conditions in New Zealand:—

"1. The recognition that not only in cities but in country districts provision should be made for instructing mothers in the care of babies; teaching young girls all practical methods of home making, including baby hygiene and feeding; giving proper hospital care to sick babies, and maintaining conferences where mothers can have their children examined and can thus learn of any bad condition before it has progressed beyond recovery.

"2. The need of definite knowledge of just what the problem is in the different communities. This knowledge it is not possible to obtain in many districts of the United States, because, on account of the incomplete registration of births and deaths, this country does not know how many babies are born and how many die. Therefore, to urge the passage of good registration laws in states in which such laws do not exist and to force efficiency in administering the registration laws in other states is a definite requirement.

"3. The need of coöperation between volunteer and public health authorities in reducing the infant mortality.

"4. Recognition of the merit of the methods of the New Zealand Society for consideration by club women and others in making plans for infant-welfare campaigns in rural communities in the United States.

"5. The value of methods which include districting the territory in a state and organizing local committees having supervision of the welfare work; the employment of nurses whose

services are chiefly educational; newspaper publicity, and the publication of pamphlets and other literature on hygiene and the care of babies and children, containing advice vouched for by the best medical authorities and expressed in direct, simple methods."

It would seem that methods which have so well succeeded in the community of New Zealand might to advantage be adopted to meet the same problem in our own country.

Correspondence.

A PHENOMENON OF ARTIFICIAL RESPIRATION.

22 APRIL, 1914.

Mr. Editor: Some time ago, I communicated to you in a letter (which you courteously did me the honor to publish in the issue of your JOURNAL for Sept. 26, 1912, Vol. clxvii, p. 453) a phenomenon of artificial respiration, which I had then observed for the first time, and which consisted in the passage of air completely through the alimentary tract of a badly asphyxiated newborn baby undergoing mouth-to-mouth insufflation.

Last week I repeated this observation in the case of a baby born by Caesarean section, in whose attempted resuscitation I had the privilege of assisting. Mouth-to-mouth insufflation was employed, as in the previous case, and within a few moments the passage of air-bubbles from the rectum, synchronously with each insufflation, was observed. The sphincter was completely relaxed, and the amniotic fluid had been considerably stained with meconium *in utero*.

The constant passage of air through the alimentary tract caused considerable abdominal distention, which was partly relieved by passing a catheter into the stomach. The distention, however, did not seem to embarrass the cardiac action, which continued regular and of good quality. For a time the baby breathed fairly well, but seemed to suffer from inspiratory dyspnea, such that mouth-to-mouth insufflation again became necessary, with the same air-bubble phenomenon as before.

After two and one-half hours, the baby's condition became so precarious that a low tracheotomy was done in the hope of relieving the respiratory obstruction. A catheter was then passed through the tracheotomy tube, and oxygen forced directly into the lungs. For a time the baby's color improved; but it failed to establish spontaneous respiration and died with the ultimate decline and cessation of the heart-beat.

Unfortunately no autopsy was permitted, so it could not be determined whether the obstruction was due to an enlarged thymus, as was suspected. In any event this second occurrence of the air-bubble phenomenon in a fatal case of infantile asphyxia seemed to me of sufficient interest to call to the attention of your readers. I am inclined to believe that it could occur only in cases in which the asphyxia had caused complete intestinal paralysis, and, therefore, is always of very serious prognosis.

Very truly yours,

ROBERT M. GREEN, M.D.

78 Marlborough St., Boston.

SOCIETY NOTICES.

NEW ENGLAND PEDIATRIC SOCIETY.—The thirty-second meeting of the New England Pediatric Society will be held at the Boston Medical Library at 8.15 p. m., on Friday, May 1, 1914.

The following papers will be read:

1. "The Fasting Metabolism of Infants," Hans Murschhauser, Ph.D., Düsseldorf, Germany.
2. "Some Developmental Causes of Poor Health in the Child: Their Importance to the Adult," John Bryant, M.D., Boston.
3. "Myotonia Congenita: With Report of Cases," Charles Hunter Dunn, M.D., Boston.

Light refreshments will be served after the meeting.

C. A. PRATT, M.D., *President.*

FRITZ B. TALBOT, M.D., *Secretary.*

MASSACHUSETTS SOCIETY OF EXAMINING PHYSICIANS.—A meeting of the Society will be held at the Hotel Westminster, April 30, 1914. Addresses through the courtesy of the Surgeon-General of the Army by Lieut.-Colonel Henry A. Shaw and Major George M. Ekwuzel of the Medical Corps of the Army. Subject: "Medicine and Surgery in the United States Army."

Dinner at 6.00 p. m. Address at 7.30 p. m.

J. H. STEVENS, M.D., *Secretary.*

NATIONAL CONFERENCE OF TUBERCULOSIS SECRETARIES.—The second annual meeting of the National Conference of Tuberculosis Secretaries will be held at the New Willard Hotel, Washington, D. C., May 7 and 8, 1914.

THE MISSISSIPPI VALLEY CONFERENCE ON TUBERCULOSIS to be held in Memphis, May 12, 1914, at time of National Conference of Charities and Correction. Conference called by A. E. Kepford, State Lecturer of the Department of Tuberculosis of the Iowa State Board of Control, and James Minnick, Secretary of the Illinois State Association for the Prevention of Tuberculosis.

RECENT DEATHS.

DR. CHARLES HUNT PORTER, who died on April 17, in Taunton, Mass., was born at Quincy Mass., in 1871. He obtained his preliminary education at the Adams Academy in that city, and received the degree of A.B. from Harvard College in 1892. He first studied theology, and was ordained to the ministry in 1895. He then entered the college of Physicians and Surgeons, of Columbia University, from which he received the degree of M.D. in 1908. He practised for a time at Springfield before settling in Taunton. He is survived by his widow.

DR. CHARLES PICKERING PUTNAM died at his home in Boston, April 22, 1914, aged 69 years. He was born in Boston Sept. 15, 1844; was graduated from Harvard College in the class of 1865 and from the Harvard Medical School in 1869. He became a Fellow of The Massachusetts Medical Society in this year. He was one of the founders of the Boston Medical Library in 1875 and had served on its executive committee and committee on library and finance continuously until his death.

DR. M. M. JOHNSON, who died at Hartford, Conn., March 15, 1914, was born at Malone, N. Y., April 21, 1844. He graduated from Brown University in 1870 and received his M.D. degree from the University of New York. He was one of the foremost surgeons of New England for many years, writing numerous articles for medical journals.

ASSIGNMENTS OF NAVY SURGEONS.

DR. F. W. F. WIEBER, medical director at the Charlestown (Mass.) Navy Yard, has been detached from duty there and detailed to the Portsmouth (N. H.) Navy Yard.

DR. N. J. BLACKWOOD has been assigned to duty at the Charlestown Navy Yard.

Original Articles.

RESULTS OF THE SWIFT-ELLIS INTRADURAL METHOD OF TREATMENT IN GENERAL PARESIS.*

By A. Myerson, M.D., Taunton, Mass.,

Clinical Director and Pathologist, Taunton State Hospital.

One of the most important contributions of 1913 in the field of syphilis was the introduction by Swift and Ellis[1] of intradural injections of salvarsanized serum. Since the technique and underlying principles of this treatment have been detailed by the original workers, and subsequently described by Hough[2] and others in reports upon cases treated by the method, it is superfluous, in this report on the fate of cases treated, to describe the technique used. It may be said that it was in all respects similar to that used by Swift and Ellis. A brief preliminary statement of the results obtained in the treatment of these cases was published in the annual report of the Psychopathic Hospital.[3] At that time I stated that the treatment could influence the course of paresis in that it was possible by using it to change the Wassermann reaction from positive to negative, and materially to reduce cell count and globulin content. In a later paper dealing with albumen content of the spinal fluid I have made some further observations on the subject, and now wish to supplement my previous report by a more detailed account of the further history of the individuals treated by this method.

The material was drawn from the cases at the Psychopathic Hospital, Boston, Mass. All here reported are paretics. Some of the cases have been under observation and treatment for a year, others for a less time, but enough treatment was administered and examinations were made frequently enough to establish in my opinion the conclusions which will be presented at the end of this paper.

Following are the cases, with a brief account of the initial condition, the record of treatments administered, the results in spinal fluid and blood, clinical changes and condition at present. It will be understood that only noteworthy changes or conditions are here recorded. The Wassermann test in each case and at all times was made by the Harvard Medical School, Department of Neuropathology. The cell count, globulin and albumen content tests were made by myself except in a very few cases.

* Being Psychopathic Hospital Contribution 1914.6, the previous contribution 1914.5 by M. C. Jarrett entitled "The Function of the Social Service of the Psychopathic Hospital, Boston," to appear at a later date in the Boston Medical and Surgical Journal.

Case 1. No. 11341. T. J. L., male, aged 40 years. Entered the Psychopathic Hospital Jan. 3, 1913. *Physical signs.* Irregular pupils, right greater than left; light reaction of left pupil, 0; right pupil, slight reaction to light; convergence reaction present. Arm reflexes, much exaggerated. Knee jerks equal and much exaggerated. Ankle jerks, absent. Homolateral and contralateral adductors, present. Right cremaster, slight; left, O. K. Right abdominal, slight; left, O. K. Speech impaired. Mentally: Delusions of persecution, slight memory defect, orientation slightly impaired as to place. Euphoric, verbose and irrelevant in conversation. Wassermann reaction in blood and spinal fluid positive. Thirty-five cells per cubic mm.; globulin, markedly increased; albumen, markedly increased. Diagnosis, unqualifiedly, general paralysis.

Treatment. Feb. 15, .6 gr. neosalvarsan.

Feb. 15, serum shows 10 cells, glob. +++ positive, alb. +++ positive. No intradural treatment given.

Feb. 27, .9 gm. neosalvarsan.

March 1, intradural treatment, 30 c.c. serum. Spinal fluid at this time shows 5 cells, globulin, positive.

March 11, .9 gm. neosalvarsan. Wassermann reaction in serum negative. Globulin ++; no cells. Wassermann in spinal fluid positive.

March 17, 30 c.c. serum intradurally.

April 9, .9 gm. neosalvarsan.

April 11, 30 c.c. serum injected. Spinal fluid at this time ++0 for globulin, +++ albumen, 0 cells. Wassermann reaction, serum slightly positive.

April 16, Wassermann reaction in spinal fluid from previous lumbar puncture reported negative.

April 22, .9 gm. neosalvarsan.

April 24, 30 c.c. of serum intradurally. Slight blood in spinal fluid, therefore no accurate examination possible.

April 26, Wassermann reaction, spinal fluid from the above specimen negative.

May 1, Wassermann reaction, serum negative.

May 7, 45 gm. neosalvarsan.

May 10, 20 c.c. serum. Wassermann reaction, serum negative. Glob. ++0, alb. ++0, few cells.

May 21, .9 gm. neosalvarsan.

May 24, 20 c.c. serum intradurally. Wassermann reaction, serum negative. Wassermann reaction, spinal fluid positive.

May 29, Wassermann reaction, serum negative.

June 25, .9 gm neosalvarsan

July 10, .9 gm. neosalvarsan.

July 12, Wassermann reaction, serum negative.

Aug. 6, .9 gm. neosalvarsan.

Aug. 9, Wassermann reaction, serum.

Aug. 13, Wassermann reaction, spinal fluid negative.

Aug. 26, .9 gms. neosalvarsan.

Aug. 30, 30 c.c. serum intradurally.

Aug. 30, Wassermann reaction, serum negative.

Sept. 3, Wassermann reaction, spinal fluid negative. Glob. ++0, alb. ++0, no cells.

Treatment was discontinued at this time. During this time the patient's mental condition did not particularly change. He was still somewhat irrelevant—foolish rather than demented, euphoric, but with no definite delusions or hallucinations. Physical signs not changed.

Oct. 24, patient showed evidence of slight confusion during the last few days, restless, speech defect more marked.

Oct. 27, patient had a slight convulsive seizure. In November he had very many general convulsions.

Physical Examination at the Present Time. He lies in bed, has lost weight and is very weak. His speech defect is more marked. The physical signs have not altered except for the fact that the cremasterics and abdominal reflexes have disappeared. He is disoriented, has no appreciation whatever of the situation, is euphoric, talks continually of what he is going to do in his work and has big plans for the future.

Wassermann reaction in blood, positive. Spinal fluid examination. Wassermann reaction, +, albumen, globulin and cell count not reported.

Summary. Patient received ten treatments of Neosalvarsan in less than one year's time. He received in addition seven intradural treatments of salvarsanized serum. The results have been mainly limited to the disappearance of the Wassermann reaction, to the reduction in the globulin, albumen and cell count. It will be seen, as I have pointed out in a paper on Albumen Content in Spinal Fluid, previously cited, that the Wassermann reaction and the cell count have been the most variable of the reactions. As far as his mental condition goes, many a paretic without treatment will show as stationary a course for a year. In other words, there has been no obvious effect of the treatment on his mental or physical condition. Following the discontinuance of the treatment by a little over a month, there came on what usually portend the final stages of paresis, namely, convulsions. At the present time the picture presented is that of a much deteriorated paretic in bad physical condition.*

CASE 2. No. 11378. C. S., male, aged 45 years. Tabes of long standing. Entered the hospital on Feb. 1 in an exceedingly maniacal, euphoric condition. The physical signs in this case were those of marked tabes, ataxia, absent reflexes, Argyll-Robertson pupils, history of lightening pains, etc., plus a mental condition of extreme psychomotor activity, euphoria, ideas of grandeur.

Wassermann reaction in the blood, positive. Wassermann reaction in the spinal fluid, positive. Since there was a slight mixture of blood in the spinal fluid, globulin, albumen, and cell count were not made at that time.

Treatment. Feb. 8, .55 gm. neosalvarsan.

Feb. 13, .9 gm. neosalvarsan.

Feb. 17, 30 c.c. of serum injected intradurally. Patient struggled and bloody spinal fluid was obtained, which was of no value for diagnosis.

Feb. 27, .9 gm. neosalvarsan.

March 1, 30 c.c. of serum. Wassermann reaction + in the spinal fluid Glob. +++, small cell increase — 5 cells.

Mar. 11, .9 gm. neosalvarsan.

March 14, 30 c.c. of serum. Wassermann reaction, blood positive. No cells in spinal fluid; no glob. Alb. +, increased moderately. Wassermann reaction, March 11, serum positive.

Patient became so boisterous, so troublesome and destructive that it was found necessary to transfer him to the Boston State Hospital, main department. His condition showed no appreciable change. He was still maniacal, euphoric. The physical signs showed no abatement. He was later transferred to Worcester.

Summary. Four treatments of Neosalvarsan; three intradural injections within the space of six weeks. No improvement clinically. Serum unchanged. Spinal fluid showed no cells, no globulin, but in this case there is no record of the original cellular and globulin content of the spinal fluid because of contamination with blood.

CASE 3. No. 11409. H. N., male, aged 39 years. Admitted Feb. 14, 1913. Came from Boston City Hospital where he had been for three weeks. Marked delusions of persecution, hallucinations of sight and hearing, intensely agitated, excited and restless. Argyll-Robertson pupils. Knee jerks present, moderately active. Ankle jerks present, moderately active. Wassermann reaction, blood positive. Wassermann reaction, spinal fluid positive. Cell count, 50 per cubic mm.; alb. +++, glob. +++. Clinical diagnosis, general paralysis.

After patient had been in the hospital a very short time his delusions and hallucinations vanished, so that by the middle of March, or a month after his admission, he was completely clear, a fact which cannot be ascribed to his treatment since betterment had commenced before the treatment was instituted. A note dated Feb. 26, before the treatment was instituted, says, "Insight is quite re-established."

Treatment. Feb. 27, .45 gr. neosalvarsan.

March 1, 30 cc. serum. Spinal fluid not examined.

March 15, 20 c.c. serum injected in spinal canal. (Serum was removed one hour after salvarsan was injected. Delay in intradural treatment due to other causes.) Spinal fluid examination at this time—no cells, glob. ++0; alb. ++0. Wassermann reaction spinal fluid, +. Wassermann reaction in blood +.

April 3, .9 gm. neosalvarsan.

April 5, 30 c.c. serum. Cells 30, glob. +++.

April 16, .9 gm. neosalvarsan.

April 19, 30 c.c. serum intradurally. Wassermann reaction, serum negative. Glob. ++0. Red cells in spinal fluid.

April 23, spinal fluid removed on the 19th reported negative.

April 30, .9 gm. neosalvarsan.

May 1, 30 .cc. serum intradurally. Cells 25, glob. ++0. Wassermann reaction, serum suggestion of positive. Spinal fluid, negative. Reported on May 7.

May 15, .9 gr. neosalvarsan. Wassermann reaction, serum slightly positive

May 21, Wassermann reaction, spinal fluid slightly positive.

May 28, .6 gr. neosalvarsan.

June 4, 20 c.c. serum intradurally.

May 31, Wassermann reaction, serum negative.

June 4, Spinal fluid slightly positive. At this time the patient was discharged on visit—condition improved.

* Since this paper was written this patient has died. Autopsy showed characteristic signs of general paresis.

June 30. Patient returned to hospital. Insomnia, which was now his principal complaint, increased upon leaving the hospital to such a point that he found it necessary to return.

July 5, .9 gr. neosalvarsan.

July 8, Wassermann reaction, serum slightly positive.

July 10, 30 c.c. of serum injected intradurally.

July 12, Wassermann reaction, spinal fluid negative. Cells 0; glob., slightest possible amount; alb., moderately increased.

July 30, .9 gr. neosalvarsan.

Aug. 2, Wassermann reaction, serum suggestive of positive.

Aug. 13, .9 gr. neosalvarsan.

Aug. 16, Wassermann reaction, serum negative. Spinal fluid not reported on.

Aug. 28, .9 gr. neosalvarsan.

Aug. 30, Wassermann reaction, serum negative. At this time treatments were discontinued.

Sept. 13, Wassermann reaction, serum slightly positive. Spinal puncture done Sept. 13, cells, 50; glob., positive; alb. increased. Wassermann reaction, spinal fluid positive.

Nov. 7, Wassermann reaction, spinal fluid positive. Lumbar puncture at this point, 1 cell; globulin, tested by Nonne's method, positive; by Noguchi's method, negative; albumin, slightly increased. (These last two lumbar punctures and examinations done by W. F. Cook of the Psychopathic Hospital.)

Dec. 24, Patient was transferred to the Taunton State Hospital. Diagnosis at that time, general paralysis of the insane. Condition reported improved.

Physical examination at the Taunton State Hospital on December 26, 1913: Patient is pale and has marked tremor. Argyll Robertson pupils. Arm reflexes are markedly increased. Knee-jerks are moderately active—right, active. Left Achilles is abolished; right, slight. The left abdominal reflex is lively—right, abolished. Cremasterics, active. Sensation in tact.

Mental Examination at this time: Patient is well oriented as to time, place and person. Grasp on the situation is good. Insight is fair. He knows his disease and knows its usual course. Remembers most of the disease, and gives the story of his life in a coherent fashion, and is accurate on details. He insists that he has inherited syphilis. Delusions are of a hypochrondriacal nature. He insists that he hears the bugs creeping around in his brain, feels them jumping from one place to another, feels them burrowing under his skin, and when a specimen of his blood is shown he insists that he can see the bugs in the blood. He holds his hands to the light and examines them by the hour to see if the bugs are there. No other delusions, and no hallucinations except the one regarding the bugs.

Wassermann reaction in the blood, positive. Wassermann reaction in spinal fluid doubtful. No cells seen; very slightest trace of globulin; very moderate increase in albumen.

Summary. Remission occurred before treatment was instituted. Following the treatment it will be noted that the Wassermann reaction was the most variable sign, disappearing both in blood and spinal fluid, reappearing. The cell count has been abolished once, but showed great variability, and it is especially noteworthy that at the end of the treatment the number of cells was 50. A month and a half later, *without any treatment*, the cells diminished to one, and at a still later examination they disappeared entirely. The globulin, it will be noted, disappeared on two occasions, and was, however, relatively more constantly present than the cells or Wassermann. The albumen increase was the most constant sign of all and showed the least fluctuations, although it had nearly reached the normal at the last examination.

Patient is to receive further treatment, but it is to be said that his physical condition is gradually growing worse. He looks paler than he did on entrance to the Psychopathic Hospital, and he is abjectly miserable. Moreover, the psychosis seems to be traveling malignly for he is now distinctly deluded regarding the "bugs," a symptom not noted until lately.

CASE 4. No. 11452. S. H. S. Male. Admitted Feb. 25, 1913, voluntary patient; aged 36 years, attorney by occupation.

Fairly good family history. Patient has always been nervous. He drank moderately and was an inveterate smoker. Thirteen years ago he had the initial lesion and went to Hot Springs for treatment. Treatment followed this, irregularly. Admitted to the bar four years ago, not successful.

Present Illness dates back from Dec. 1, 1912. Despondent, downcast and unhappy. He has made two attempts at suicide, once by taking trional, and again by bichloride of mercury. No hallucinations or delusions. Sleepless, no appetite. Arms and legs feel numb. Immediate cause of psychosis said to be the breaking off of his engagement with a young woman he intended to marry. This the patient did to protect the young woman.

Physical Examination. Right pupil larger than the left. Argyll-Robertson on left—slight reaction to light on right side. Knee jerks and ankle jerks lively. Arm reflexes exaggerated. Sensation not disturbed. Periosteal reflexes active. Abdominal reflexes, uppers gone, lowers, O. K. Cremasterics present. Wassermann reaction, serum positive. Spinal fluid positive to Wassermann, 40 cells, globulin increased, albumen increased.

Treatment. March 3, .45 gr. neosalvarsan.

March 7, serum, 30 c.c. Wassermann reaction, spinal fluid positive.

March 19, .9 gr. neosalvarsan.

March 21, serum, 30 c.c. No cells, glob. slight. Wassermann reaction, spinal fluid positive.

April 3, .9 gr. neosalvarsan.

April 5, 30 c.c. serum. Glob. +++, 25 cells, alb. increased

April 16, .9 gr. neosalvarsan.

Apr. 19, 20 c.c. serum intradurally. Wassermann reaction, serum positive. Glob. ++, cells 30, Wassermann reaction, spinal fluid negative.

April 22, .9 gr. neosalvarsan.

April 26, spinal fluid positive.

April 30, .45 gr. neosalvarsan. Wassermann reaction, serum negative.

Physical examination at this time disclosed no great difference from previous examination. Men-

tal examination disclosed no definite signs of a psychosis. At this time, however, he found himself examining words that came to his mind in something the following manner. For example, the word "echo" as it came to his mind in sentences brought forth questions as follows: "What is an echo?" "What does the word 'echo' mean?" "Are there many echoes?" "Do woods give echoes?" His mind would busy itself answering those questions, and at the same time he recognized the absurdity of his own activity. He stated that this symptom was most constant and that it had no particular emotional content, that is, no particular words or sets of ideas were continually reacting. Still very sleepless and can see no betterment in his condition. Has perfect insight. Is willing to be treated and thankful for attention given him. Is on the whole rather hopeless.

Concerted and persistent effort will usually elicit a correct reply to any question in educational matters, but the patient's first tendency is to say, "I don't know" to anything at all difficult. In other words, he thinks his memory is gone. This symptom is important in view of later developments.

May 10, Wassermann reaction, serum slightly positive.

May 21, .9 gr. neosalvarsan.

May 24, 30 c.c. serum intradurally.

May 24, Wassermann reaction, serum positive.

May 29, Wassermann reaction, serum suggestive of positive.

June 4, .6 gr. neosalvarsan.

June 7, Wassermann reaction, serum positive. 20 c.c. intradurally.

June 11, Wassermann reaction, spinal fluid slightly positive. Glob. 0, cells 0, alb. slightly increased.

July 2, .45 gr. neosalvarsan. Wassermann reaction, serum positive.

July 7, Wassermann reaction, serum positive. Spinal fluid, not examined for cells or globulin.

July 10, Wassermann reaction, spinal fluid negative.

July 16, .45 gr. neosalvarsan. Wassermann reaction, serum slightly positive.

July 19, 30 c.c. intradurally. Wassermann reaction, serum slightly positive. Wassermann reaction, spinal fluid moderately positive.

July 30, .45 gr. neosalvarsan.

Aug. 13, .6 gr. neosalvarsan.

Aug. 14, 30 c.c. salvarsanized serum, last treatment. Spinal fluid, Wassermann reaction slightly positive.

Aug. 16, Wassermann reaction, serum slightly positive.

Aug. 26, Wassermann reaction, serum negative.

Sept. 13, Wassermann reaction, serum negative.

Dec. 16, transferred to main department of Boston State Hospital.

Physical Examination. Pupils show same changes as before, as do the other physical signs. Condition, unimproved.

Jan. 20, examined by present writer. Physical signs as above stated. Patient is thinner, however, than when at the Psychopathic Hospital, and the mental examination shows a distinct change in the emotional tone. While he still claims that there is no hope for him, his whole attitude is euphoric. Voice is loud, manner is breezy, and he laughs in a silly manner at times. He states in an irrelevant fashion that his brother is coming to see him and bring him some candy and cake, whereas such a visit when patient was first seen at the Psychopathic would have been passed over by him as too trivial to mention to the physician. Now he mentions it with great gusto. He says, "My memory is as good as it ever was. I remember every little thing in detail. My memory is excellent." This is in marked contrast with his attitude at the Psychopathic when he was complaining continually of his memory. The facial movements are somewhat more stiffened and exaggerated. Otherwise he gives no definite mental signs of general paresis. Wassermann reaction, serum negative. Spinal puncture refused.

Summary. Patient received eleven doses of neosalvarsan intravenously and seven intradural injections. Wassermann reaction in serum and blood became negative at times. At one time the globulin disappeared as did the cells. He showed no improvement, however, in his clinical manifestations although for a long time he showed no downward change. When the treatment was discontinued, there seemed to have followed an emotional deterioration, manifested at the present time by a mild euphoria and triviality. On the whole it is possible that the treatment in this man's case halted the disease for a short time, but that it did not seriously alter its progress is manifested by the impaired physical condition at the present time, and the gradual, if not obvious, mental breakdown, this despite the fact that Wassermann reaction at present is negative.

The next case is recorded in this series because the patient had four injections into the spinal canal and refused further treatment in this manner because of the violent reaction. However, he had ten doses of neosalvarsan, and offers an excellent comparison with the other cases.

CASE 5. No. 11415. J. H. S., male, aged 48 years, married.

Family History. Negative. In 1904 the case was diagnosed as locomotor ataxia at the Boston City Hospital. The gait has been unsteady for years—pains in the legs. About six years ago patient became rather irritable and has grown more so of late. One month ago he called his wife and said that he had a vision, and told her to hide all the knives. Cried a good deal.

Physical Examination. Argyll-Robertson pupils. Arm reflexes present, knee and ankle jerks 0. Diminished sensation to pain in a belt-like fashion around the chest. Memory defect noted in recalling the three last governors. Arithmetical tests are poorly answered. No hallucinations or delusions noted. Emotional tone somewhat euphoric. For a diagnosis of paresis, there are but few mental signs, but the history of irritability, the memory defect and the euphoria point decidedly that way. Tabes is without a doubt present. Wassermann reaction in blood, positive. In spinal fluid, suggestive of positive, 40 cells; globulin much increased.

Treatment. Feb. 20, .45 gr. neosalvarsan.

Feb. 22, 25 c.c. serum.

Feb. 24, report on blood taken before intradural injection, serum negative.

March 6, .9 gr. neosalvarsan.

March 8, 30 c.c. serum; 0 cells, glob. ++. Wassermann reaction, serum.

March 19, .9 gr. neosalvarsan. Wassermann reaction, serum negative.

March 22, 12 c.c. serum. Wassermann reaction, spinal fluid negative No cells, glob. +, alb. moderately increased.

April 9, .9 gr. neosalvarsan.

April 12, 30 c.c. serum. Glob. ++, cells 0. Spinal fluid negative.

From this time the patient refused any intradural treatment.

April 16, .45 gr. neosalvarsan.

April 22, .45 gr. neosalvarsan.

April 26, Wassermann reaction, spinal fluid negative. Glob. very slightly plus, cells 7.

April 30, .45 gr. neosalvarsan. Wassermann reaction, serum negative.

May 7, .45 gr. neosalvarsan.

May 10, Wassermann reaction, serum negative.

May 21, .9 gr. neosalvarsan. Wassermann reaction, serum negative.

May 24, Wassermann reaction, serum negative.

June 4, .9 gr. neosalvarsan. Wassermann reaction, serum negative.

Record does not contain treatment after this. The symptoms did not change except that the patient claimed to have less pain in his legs. In December he was transferred to the main hospital; condition clinically unimproved.

Jan. 20. Examined by writer. Much thinner than upon entrance to the hospital. Optic atrophy marked. Memory fairly good. Euphoria extremely marked. Said to the examiner, "See how well I walk now days," and proceeds to demonstrate. Gait is extremely ataxic and unsteady. Diagnosis by staff of Boston State Hospital, tabo paresis. Wassermann reaction, blood negative. Wassermann reaction, spinal fluid, not made since lumbar puncture was not permitted.

Summary. Early case of paresis—late case of tabes. Four intradural injections with changes after the first intravenous so far as Wassermann reaction is concerned. This reaction disappeared from the blood and spinal fluid almost immediately upon treatment, but seems to have been due to salvarsan more than any other factor in the treatment. Despite its absence, the condition of the patient showed no definite improvement, and shortly after treatment was stopped his condition became distinctly worse. Here too the Wassermann reaction is negative.

CASE 6. No. 11737. F. M. L., male, aged 39 years, married. Entered May 6, 1913. The occasion of this patient's commitment to the hospital was a sudden outbreak in the house of a friend. He threw an Indian club out of the window, and then chased a small boy who had taken it down the street, screaming in a maniacal fashion. Family history negative. Had a high school education. He had been a spendthrift, a heavy drinker, and has led a dissolute life. At first he denied syphilis, but later admitted having had it years ago. At the time of entrance he was clearly oriented. Memory seemed intact. No hallucinations or delusions were elicited. He was somewhat euphoric. Continually attempted to leave the hospital. Rather verbose in answers. Otherwise showed no distinct mental symptoms.

Physical signs were carefully noted at that time. The left pupil was slightly larger than the right, both reacted moderately to light, consensual and distance. Cranial nerves of the face were good. No paralysis anywhere. Slight tremor of the hands. Reflexes of the arms were equal and moderate. Knee jerks, equal and active. Ankle jerks equal and active. No Babinski, Gordon or Oppenheim. Adductors moderate. Cremasters and abdominals O. K. In other words, physical examination was almost entirely negative. Blood serum positive to the Wassermann reaction to syphilis. Spinal fluid showed moderate pressure, albumen much increased, Wassermann negative, globulin by Nonne's method very slightly positive, likewise by Noguchi's method; cells mostly reds, of which there were perhaps 1000 in the field. No blood had been drawn upon puncture, and these cells it was evident had not come from the puncture since the slightly yellowish tinge of the spinal fluid could not be centrifuged out. This peculiar spinal fluid had its explanation a very short time afterward in the following:

May 11. During the morning the patient was confused, restless, and attempted to get out. At 12.30 he suddenly lost consciousness, became rigid, and showed some clonic movements. Recovered in about thirty minutes. During this time there was a double Babinski, more on the right side, rigid pupils, absence of cremasteric and abdominal reflexes. At six p.m. he was up and around, very euphoric, and markedly confabulating. He told how he had been out all day in an automobile and spoke of the very elaborate meals which he had had. Showed marked loss of memory for recent events. Was disoriented for time and place. Gave irrational answers to questions on educational matters. Lumbar puncture done at this time shows that spinal fluid was under high pressure, was yellowish in color, contained very many red cells, although no blood had been drawn by the puncture, and as before, the color could not be centrifuged out.

The Wassermann reaction in the blood was still positive. At this time there was positive Wassermann reaction of spinal fluid. The globulin was distinctly positive.

From this time for a period of one month, the patient had marked euphoric delusions. He was to marry a nurse of the ward. He had $50,000, a motor boat, and a Pierce-Arrow automobile was to take him and his bride all over the country and to Europe. He denied that he was married, and said most emphatically that the nurse, who was possessed of all the virtues of her sex both in person and character, had promised her hand to him as soon as he could get out. He had schemes for making money. Gradually this euphoric state disappeared.

Treatment. May 14, .45 gr. neosalvarsan.

May 21, .45 gr. neosalvarsan.

May 24, 20 c.c. serum intradurally. Wassermann reaction, serum positive.

May 28, .9 gr. neosalvarsan. Wassermann reaction, serum negative.

May 31, 30 c.c. serum intradurally. Wassermann reaction, serum negative.

June 6, .6 gr. neosalvarsan.

June 7, Wassermann reaction, serum slightly positive. 20 c.c. serum injected intradurally. Spinal fluid at this time showed still the slight

yellowish tinge, although no red cells were to be seen. This yellowish tinge persisted for some time, and was probably due to hemoglobin and to dissolved coloring matter from the red cells. Finally it disappeared and the fluid became clear.

June 11, 45 gr. neosalvarsan. Wassermann reaction, spinal fluid negative.

June 14, Wassermann reaction, serum positive.

June 19, .9 gr. neosalvarsan.

June 21, 30 c.c. serum intradurally. Wassermann reaction, serum negative. Spinal fluid, suggestion of positive.

July 2, .9 gr. neosalvarsan.

July 7, 30 c.c. serum intradurally. Spinal fluid at this time, 5 cells, glob. slightly +, alb. distinctly increased. Suggestive positive Wassermann. Serum, slightly positive.

July 16, .9 gr. neosalvarsan.

July 19, 30 c.c. serum intradurally, 10 cells; glob. +++, alb. increased. Wassermann reaction, serum negative; spinal fluid, negative.

July 30. .9 gr. neosalvarsan.

Aug. 2, Wassermann reaction, serum positive.

Aug. 9. Another physical and mental examination was made. He does not remember the two weeks following the convulsion. Following that, however, his memory is clear. He laughs at his former delusions concerning the nurse and likewise those concerning his wealth. He spontaneously states that he had been losing memory for some time before he came to this hospital, likewise losing his ambition, and that he was cranky at home. No pains. Occasional dizzy spells. Physical examination at this time shows very important changes. The right pupil showed almost no reaction to light. The left showed prompt consensual and light reaction. The right arm reflex is lively, greater than the left. Right cremasteric is greater than the left. Knee jerks are equal. Right ankle jerk is active. Left ankle jerk is very slight. No Babinski, Gordon or Oppenheim. Mental examination showed no distinct defects by the Binet-Simon and Healey tests. By careful psychological tests for memory defect and by the ordinary psychiatric examination, nothing of pathological nature was found. He took an active part in the social life of the ward and was one of the leading spirits amongst the patients.

Aug. 13, .9 gr. neosalvarsan.

Aug. 16, 30 c.c. serum intradurally. Wassermann reaction, serum slightly positive. Wassermann reaction, spinal fluid negative.

Sept. 13, serum positive. Treatment discontinued.

Oct. 29, note was made that his condition was unchanged.

Dec. 24, discharged to the Taunton State Hospital. Diagnosis, general paralysis. Condition, unimproved.

At the time of discharge from the Psychopathic Hospital, the patient had commenced to become grandiose again. He exhibited eccentricities of conduct and is said to have a hysterical outburst. This outburst, the patient describes differently. He states that he had a numb feeling in his head and a numb feeling in the right hand; that while he knew the words he was to say and use, he could not utter them. Neither could he write, although he says he understood writing when it was given to him. When he attempted to make himself understood by the physicians, he spoke nonsense, and realized that it was nonsense. By his description, there was a cerebral condition of some kind, transitory in nature, marked by motor aphasia and confusion, with numbness of the right hand.

Physical examination in Taunton State Hospital on Dec. 26. At this time the pupils are Argyll-Robertson on both sides. Tremor of tongue. Blunting of sensation of right side of face. Arm reflexes as before. Left Achilles diminished. No Babinski, Gordon and Oppenheim. Cremasterics present. Left upper and lower abdominal reflexes absent, right upper present, right lower absent. Ophthalmoscopic, negative.

Mental examination at this time shows verbosity, pomposity, euphoria with delusions of grandeur, mostly of a sexual character. He is to marry Miss M., a nurse at the Psychopathic Hospital, and they are to go on a long trip together. He is to furnish a home. She is the most beautiful and virtuous of women, etc. Orientation is intact. Memory is good. No hallucinations. Acts superior to his environment. Somewhat irritable and a trouble-maker amongst the patients. Wassermann reaction in spinal fluid positive. Albumen, moderately increased, globulin moderately increased. Thirty lymphocytes. Serum positive.

Summary. This patient, at first considered to be a case of cerebral spinal syphilis, is now considered a general paretic. First, the history of cerebral accident, second the euphoria, grandiose ideas, etc., third, the gradual development of Argyll-Robertson pupils, and the gradual change in reflexes; fourth, the appearance of the four reactions in blood and spinal fluid plus the albumen increase in the latter. He has shown fluctuations in the Wassermann reaction in blood, and there was present in the spinal fluid evidence of a hemorrhage which has made its way into it. Undoubtedly the first flare-up was accompanied by a hemorrhage into some part of the brain, and it is very probable that the second development of grandiose ideas started with some cerebral attack. It is to be especially noted that the Argyll-Robertson pupils developed in this patient's case despite the use of salvarsan and the intradural method of treatment, and for that reason I think this case is of crucial importance in determining the value of the Swift-Ellis method.

CASE 7. No. 11537. J. M., male, aged 37 years. Entered the 25th of March. Family history negative. Early life of patient uneventful. Married, four children, no miscarriages. Two years ago he was thrown from a horse and broke three ribs—recovered. Somewhat later he had "trouble with his head," of indefinite kind—recovered. About Christmas before entrance he began to act queerly. Became careless, worrisome, nervous, could not sleep, forgetful of recent events, and at times irritable and untidy.

Physical Examination. Argyll-Robertson pupils, exaggerated reflexes, some unsteadiness of gait. Mentally: Disoriented for time, no grasp of surroundings, poor memory, loss of educational facts, some euphoria, retardation in answers, and impaired insight. Serological examination showed positive Wassermann in blood, positive Wassermann

in spinal fluid. One hundred cells in spinal fluid, markedly increased globulin and albumen.

Treatment. April 9, .9 gr. neosalvarsan.

April 12, 30 c.c. of serum intradurally.

April 16, Wassermann reaction, spinal fluid positive. Fifty cells, albumen and globulin in marked excess.

April 22, .45 gr. neosalvarsan; 30 c.c. serum intradurally.

April 26, Wassermann reaction, blood and spinal fluid positive.

May 7, .9 gr. neosalvarsan.

May 10, Wassermann reaction, serum slightly positive; 20 c.c. serum intradurally. Wassermann reaction, spinal fluid positive; 30 cells, glob. somewhat reduced, alb. much increased.

May 21, .9 gr. neosalvarsan. Wassermann reaction, serum negative.

May 26, 30 c.c. serum intradurally. Spinal fluid, Wassermann positive.

June 4, .9 gr. neosalvarsan. Wassermann reaction, serum positive.

June 7, 30 c.c. serum intradurally. Wassermann reaction, spinal fluid positive; 50 cells, globulin and albumen in excess.

June 25, patient becoming rapidly demented. Now lies in bed most of the time. Occasionally gets up and tries to put on other patients' clothing. Does not know the way to his bed and is very untidy. No insight whatever. No grasp on surroundings. Memory for recent and remote events much worse. Treatment discontinued. Transferred to Boston State Hospital, main department, on June 25, 1913. Died Jan. 23, 1914, after severe convulsions. Was bedridden most of stay in hospital.

Summary. Despite intensive treatment—five doses of neosalvarsan and five intradural injections within two months, patient grew rapidly worse, and within one year after onset, died of general paralysis. This case needs no further comment except that on entrance he did not seem worse than many other paretics who last longer.

Case 8. No. 11636. A. V. D., male, aged 57 years. This case, although not receiving many intradural treatments, received several doses of salvarsan, followed later by intradural treatments, despite which his condition rapidly grew worse.

Family history is good. Personal history not remarkable, except that he has had no children although married many years. A chancre occurred thirty-five years ago. The first symptom was bladder trouble in August of last year, incontinence of urine since that time. Insomnia. History of paralytic attack two days before entrance.

Physical Examination. Pale, thin man. Aortitis. Argyll-Robertson pupils. Very lively ankle and knee jerks. Homolateral and contralateral adductors. Skin reflexes absent. Speech defect.

Mental Examination. Poor grasp on surroundings; recent memory defect although remote memory seems good; educational tests well answered except where recent events are concerned. He is rather choleric and irritable, but on the whole formal and courteous. Flow of thought not remarkable. No insight. Wassermann in blood and spinal fluid, positive. Cell count 30, glob. and alb. increased.

Treatment. April 22, .9 gr. neosalvarsan.

April 29, seems to be slightly improved. Answers questions fairly well. Hard to please in the choice of books, which he continually asks for and reads.

April 30, .9 gr. neosalvarsan.

May 1, Wassermann reaction, serum positive.

May 15, .45 gr. neosalvarsan.

May 17, Wassermann reaction, serum positive.

May 28, .45 gr. neosalvarsan.

May 31, Wassermann reaction, serum positive. Fifteen c.c. intradurally. Wassermann reaction at this time positive in spinal fluid. Spinal fluid shows increased cell count, alb. and glob. increase.

June 11, .45 gr. neosalvarsan.

June 14, 30 c.c. serum intradurally. Wassermann reaction, serum positive. Wassermann reaction, spinal fluid positive.

July 19, Wasermann reaction, serum positive; .45 gr. neosalvarsan.

July 20, 30 c.c. serum intradurally. Wassermann reaction, spinal fluid positive; 30 cells, glob. increased.

Aug. 26, .9 gr. neosalvarsan.

Aug. 30, Wassermann reaction, serum positive.

At this point treatment was discontinued. Patient's condition was growing worse, and he seemed weaker and more demented. Bladder trouble was worse. It was impossible to arouse him to long continued conversation although when he did answer, his replies were usually correct and well expressed. Grasp on surroundings very poor.

Sept. 13, note says, "Patient has grown progressively worse. Died today at 4.15 a.m." Autopsy disclosed the usual cerebral and cord findings of general paresis.

Summary. A man who received seven doses of neosalvarsan, and three doses of intradural therapy, despite which he grew rapidly worse and died. There was nothing in the clinical history of his case to distinguish it from that of many another man in the late fifties who acquires paresis. Such cases usually last but a short time, and the salvarsan and intradural treatment probably had no influence either in hastening or retarding his death.

Five other cases treated by the intradural method are not here recorded. Of these, one was a tabetic, and, therefore, his record is not pertinent to the question of the value of the use of the intradural method in paresis. It may be stated, however, that it seemed to do but very little good in his case, and even the gastric crises and lightning pains, which it is claimed this treatment helps, were but little affected.

The second case has been diagnosed as cerebral spinal syphilis although it is my opinion that the patient is suffering from general paresis. This patient showed marked improvement, and left the hospital in a state of complete remission. However, it is well to remark that later she wrote me a note on a gorgeously emblazoned New Year's card, although the date of its sending was November 1st. Her judgment of the appropriate, at least, does not seem to have been restored to the normal.

The third patient was a case of precocious cerebral spinal syphilis who made a very good recovery. In his case, however, mercury and the iodides were used *ad lib.* and the part played by the neosalvarsan is in question. However, it undoubtedly helped, but the disease is one that does not resist treatment.

The fourth was a congenital tabetic who received only three treatments and cannot be included in this series.

The fifth was a paretic who stayed in the hospital for two treatments only. He showed no improvement, but is not here recorded because the time of treatment was insufficient.

Summary of Cases. Of these eight cases, all undoubted pareties, mostly under forty and only one over fifty, the following has been the fate: Two died (Nos. 7 and 8 in the series).* Of these, one received five doses of intradural therapy, and the other three doses. The course of both was steadily "down hill," and there is nothing in their clinical histories to indicate that their treatment had the slightest effect upon the disease. In these two cases it is to be noted that there was no change in the Wassermann reaction.

A third (No. 6 in the series), although not definitely a paretic patient on onset of treatment, and having no definite physical signs during treatment, developed in its course the Argyll-Robertson pupils and differences in his tendon reflexes. The case is a critical one for the therapy because this patient was young, robust and received treatment very early in his disease. Far more important than the fluctuation of the Wassermann reactions in his history is the appearance of these ominous physical changes. They mark a distinct progress in the lesions of paresis. Despite the clearing up of the mental signs, his case can be said to have advanced steadily, despite intensified treatment. Moreover, the disappearance of the mental signs has to be considered more in the light of a remission than as due to treatment. It is to be noted that at the onset of his disease the Wassermann reaction in spinal fluid was negative. At the present time, it is positive, so that in this respect, too, he is worse than he was. Moreover, the patient, while maintaining a robust appearance, has a pallor which William N. Graves,[5] of St. Louis describes as cachectic, that is, a sickly look with no apparent loss of hemoglobin. He looks distinctly sicker than on entrance to the hospital and before the beginning of his treatment.

Another case (No. 2 in the series) was discharged unimproved. He received only three doses of salvarsanized serum intradurally, and four doses of salvarsan. His case may be dismissed as being indifferent in its application to the question whether or not salvarsanized serum is of benefit to paresis. It is true that the spinal fluid showed changes, but how far these are related to definite improvement is one of the points at issue.

The fifth case (No. 5 in the series) showed very definite serological changes. Wassermann reaction early became negative and remained negative, but it is to be remarked remained negative, although the intradural treatments had been discontinued and only neosalvarsan intravenously administered. There was no definite clinical improvement manifested. Patient said that the pains were less, but as a matter of fact this seems to have been due rather to euphoria than to actual diminution of the symptom, for at different times it was noted that he was suffering from pain. The salvarsan probably caused an enteritis in his case for a bloody diarrhea was noted several times. After the treatment was discontinued the deterioration and downward progress became marked. Nevertheless, the Wassermann reaction in blood at present is negative.

In a general way what has been said of the above case will apply to the next two cases (No. 1 and No. 4 in the series). In both of these cases the Wassermann reaction was exceedingly variable, in general favorably influenced by the treatment. Moreover, the cell count, the globulin and albumen all were reduced at various times by this treatment. There was, however, no abatement in physical or mental signs. The patients did not look better, feel better or act better. Following the discontinuance of the treatment, the progress downward was marked, showing that the treatment in no wise stopped the disease, although it may have checked it for a time. It would almost seem as if its discontinuance accelerated the normal progress, if such a term can be employed, of the disease. At any rate one cannot claim much for a treatment which when employed as consistently and frequently as in these cases, after it has been discontinued for three months, finds the patients far worse off than when the treatment was initiated.

The last case (No. 3 in the series) has shown what might seem to be the most favorable results of the treatment. A maniacal patient, deluded and hallucinated, all the reactions present in blood and spinal fluid, for a time showed a complete remission, and following the discontinuance of the treatment developed ony a few hypochondriacal ideas. Wassermann reaction at the present time is doubtful, cells and globulin almost vanished, albumen greatly reduced. At first glance this would seem to be a splendid recommendation for the treatment, but it is to be noted against this view that the remission started before the treatment was instituted and was almost complete when the first dose of neosalvarsan was administered. In a disease so eminently one of remissions, one must be exceedingly careful in interpreting what one finds as the result of treatment. There are cases on rec-

* Since this paper was written No. 1 of these cases has died, making a total of three deaths. This is a larger ratio of mortality than is usual in the first year of paresis.

ord in the Taunton State Hospital where the remission had lasted two and more years, and undoubtedly such histories can be more than duplicated by any other hospital Moreover, the patient looks worse than he did when treatment was first started His color is not so good—it is more yellowish than formerly He is more listless and despondent

CONCLUSIONS.

1. Patients receiving this form of treatment show changes probably as the result of it. These changes are mostly limited to the disappearance of the Wassermann reaction and alterations in chemical-cytological composition of the spinal fluid. On the whole, no clinical improvement can be recorded which cannot otherwise be accounted for.

2. As has been stated in a previous paper, the order of changes is somewhat as follows: The Wassermann reaction seems to be the most variable—the first to disappear, the least stable. The difficulty in evaluating the Wassermann reaction lies mostly in the fact that the results obtained by various laboratories vary according to the ability of the technician and serologist. In the case of these patients, all the work was done in one laboratory, the same method used throughout, and thus a fairly standard Wassermann reaction can be recorded.

The cell count seems to have been the next most variable constituent. It seems to be profoundly affected by the treatment, but a reduction must not be taken too optimistically. It will be noted that in the case of H. N. (No. 3 in the series) the cell count was 50 after treatment was discontinued. Later on, without treatment, it dropped to 0 for no well defined reason. Since the examiner was the same in both cases and used the same technic and care, it is probable that the record is faithful to the facts at each time.

The globulin is perhaps a little less variable than the cell count, that is it does not diminish so much under treatment, and it rarely completely disappears.

Finally, the albumen content is the most constant of all, and is least affected by treatment. (For details regarding the albumen test, see writer's paper in the *Journal of Nervous and Mental Diseases.*)

Homer Swift,[8] in a discussion before the New York Society of Neurology, stated that in his opinion the cell count was the most variable of the reactions, and the Wassermann next, both differing, however, very little from each other in their constancy. Next in permanency he found the globulin test. He does not record the albumen content. It will be seen that his results differ but little from my own, there being merely a transposition in relation between Wassermann reaction and cell count. Since the difference between the two is not very great, his findings and mine are essentially the same, except that I have added to the test recorded the total albumen content.

3. The Wassermann reaction probably is not nearly so important a criterion of improvement or recovery as it is frequently held to be. This statement is substantiated by the following facts:

First, It seems to be capricious in its appearance and disappearance. That is to say, there is no ascertainable relationship between it and the clinical conditions of the patient.

Second, As is shown in No. 4 and No. 5 of this series, the patients' condition may gradually grow worse both physically and mentally and the Wassermann reaction remain negative. This fact is perhaps the most important of those disclosed in the investigation of the treatment.

Third, It is generally assumed that a change for the better is accompanied by a Wassermann negative—a change for the worse, by a Wassermann positive. Whatever the Wassermann reaction may mean, it does not measure the full scope of the paretic process. It represents a diagnostic feature of great importance, but we must learn to separate the diagnostic facts from the pathogenetic facts.[7] The treatment here recorded changes the process of the disease in that part of it from which originates the alterations leading to the appearance of the Wassermann reaction, but unfortunately these alterations are but a part of those occurring in the total disease process.

4. What has been said of the Wasermann reaction applies in a lesser degree to the chemical and cytological changes. It is probably true that the criterion of recovery or progress at present must be in the field of the clinical manifestations.

5. Finally, it must be stated that the theoretical grounds upon which this treatment is based do not seem to me to be valid. It is assumed that because the Wassermann reaction is most constant an hour after the administration of salvarsan, therefore the blood at that time contains more anti-bodies. This, of course, is by no means certain, for the meaning of the Wassermann reaction is unknown. Furthermore, it seems to be the opinion, shared by Swift and Ellis, that the nervous system is inaccessible to medicament administered in the usual channels. One hears the term "inaccessibility of the nervous system" quite frequently, yet a little reflection shows there is no such thing. The effects of opium, chloral, bromide, alcohol, strychnia, and certain of the toxins of infectious diseases seem notably to affect the brain and nervous system, and to do this through the blood stream. The appearance of headache following all kinds of bodily disorders contradicts the assertion of the inaccessibility of the nervous system most emphatically. Further, it is assumed that the introduction of medicament into the cerebro-spinal space can affect the brain favorably and locally. Undoubtedly such administration does affect those local conditions,

which are largely meningeal, as, for example, cerebro-spinal meningitis, cerebro-spinal syphilis, gummatous conditions, etc. But in paresis the bulk of the lesions are deep and spirochetes have been discovered only in the cortical substance itself. Now the current of the spinal fluid, if there be a current, is not into the cortical substance or brain tissue. Whatever be the origin of this fluid, whether secreted by the choroid plexus, whether dialyzed from the blood stream as claimed by Metrazat, or the product of the pial endothelium, its direction is from the cortical substance and the brain tissue in general, rather than towards it. So that logically intradural treatment for paresis would fail, and the only reason that the salvarsan does not cure in the case of paresis is because there is either a lack of some intermediary substance to unite it with the spirochete or else because the spirochete has acquired new resistance by reason of its long stay in the body of its host.

Moreover, despite the discovery of Noguchi, that the spirochete pallida is present in the brain of paretics it is probable that the sum total of the paretic process is something more than chronic syphilis, or at least a degenerative process has been added, which it is difficult to stay.

There seems to be another reason for the failure of salvarsanized serum in this treatment. Granted that its theoretical basis be correct, and that the introduction into the intradural spaces can locally and favorably influence general paresis, the amount introduced seems utterly insufficient. Of all the blood in the body, 50 c.c. are removed one hour after salvarsan has been administered. Such an insignificant fraction of the total amount of the blood present can contain only a very small amount of salvarsan. Its introduction seems *a priori* to be adding but little of local treatment to that of the salvarsanized blood stream itself.

However, the treatment merits further trial. It should not be administered to every paretic in the hospital, as some men seem to feel, but should be used on selected groups of cases. It would be very wise not to hold out hopes to the relatives or to the patient, because the result will probably be disappointment. Experience with this treatment teaches much about paresis and leads to the hope that there is a cure for the disease since we now know that it can be profoundly affected, but as far as my experience goes, the Swift-Ellis method is not the looked-for cure.

I wish here to thank the Massachusetts State Board of Insanity for financing this research, and also to express my obligation to Drs. E. E. Southard, H. P. Frost, and A. V. Goss, in charge respectively of the Psychopathic, Boston State and Taunton State Hospitals, for their assistance. For a zealous coöperation that never failed in the midst of a heavy hospital routine, I hereby express my earnest gratitude to Dr. Roger R. Rupp, of Copley, Pa., formerly interne at the Psychopathic Hospital.

HIP FRACTURES AND THEIR TREATMENT.*

By Frederic J. Cotton, M.D., Boston.

For a century past, at least, fracture of the hip has been the dread of surgical practitioners, and much has been written about treatment. What has been done, or claimed, of late years as to the treatment of hip fracture has, however, largely ignored an important distinction that our predecessors, beginning with Astley Cooper, understood pretty clearly. Let us put the distinction in this way—the danger of nonunion applies only to fractures close to the head of the femur. (Figs. 3, 4, 5, 6, 14, 15, 16, 17.)

We know that impacted fixed fractures close to the head often unite, and may achieve bony union. (Figs. 10 and 11.) Loose fractures at this point stay loose. (Figs. 13, 14, 15.) How far the distinction between intra and extracapsular fractures is important, we do not know even now, but the clinical rule as given above will hold.

What has confused the question of results so long is the fact that "inter-trochanteric" fractures proceed to bony union despite surgical pessimism, despite the worst treatment. (Figs. 21 to 25.) In such fractures the possibilities of deformity are grotesque, (Fig. 23) but nonunion is negligibly rare.†

Non-union in fractures of the neck proper on the contrary is not rare, and even in cases showing apparent impaction at first, this impaction not infrequently gives way in the early weeks of treatment despite careful routine fixation. (Figs. 3, 6, 15, 16, 17.)

At best there is always some bone absorption in these cases, even when such absorption is associated with the repair process. The original impaction is modified, even though a serviceable entanglement of fragments persists. (Figs. 10 and 11.)

The methods of treatment advocated have, in a large measure, lost sight of the working classification here hinted at.

For practical purposes this classification, and

* Read for the writer by Halsey B. Loder, M.D., before the Essex North District Medical Society, October 8, 1913.

† Murphy has shown good plates of one case of non-union at this point. I have yet to meet with a case personally.

the results attained in the different classes, may be given as follows:

Fractures in the trochanteric region. These, as already noted, almost invariably unite by bone, though often with great deformity, and not rarely with some resultant disability, from sheer distortion. (Figs. 7, 8, 9, 21, 22, 23, 24, 25, 26, 27, 28, 29.)

Fractures of the neck proper.

(a) *Cracks*: They do well unless extraordinarily badly handled. (Fig. 1.)

(b) *Solid* Impactions: They unite with shortening and with more or less deformity in eversion, but solidly. The clinical results are fair to good. (Fig. 2.)

(c) *Imperfect* Impactions: The common type. In these cases, the impaction, more or less solid, tends to perpetuate a deformity in shortening and eversion, more or less extreme; in some cases the impaction gives away, or is broken up even without accident or obvious neglect of precaution. These cases then fall into the class of loose fractures to be considered presently. (Figs. 3, 16, 17, and 18.)

As a rule, however, these imperfect impactions hold until the break unites, and, in many cases at least, unites by bony union, leaving more or less disability but only *from distortion.*

This result, often the best we can hope for, is not ideal, and in the cases occurring in the more vigorous class of patients, young or old, the question, constantly recurring of late, is whether correction of deformity may not be attained without risking the prospect of firm union.

(d) *Loose fractures* of the neck. These cases differ in no way, to start with, from the impacted cases, save in the *accidental absence* of *impaction.* Unfortunately loose hip-fractures at the neck, ("sub-capital" fractures as Ruth calls them), do not unite by bone, are very apt to fail of even a serviceable fibrous union, and usually enough give a hip that is not very useful. (Figs 5, 12, 13, 14, 15, 18, 19, and 20.)

So much for the natural history of these cases, without treatment, or under average routine treatment.

The time available does not allow of proof of statements already made, but the statements rest not only on impressions, but also on the careful investigation of a considerable series of cases by the writer, (with the assistance of Dr. Andrew Cornwall) shortly to be published. Scudder's published results confirm our data.

Now, as to treatment: We have to choose from—

(a) The old routine; fixation, with or without traction.

(b) The Shaffer-Whitman method.

(c) Senn's pressure method.

(d) Phillips-Maxwell-Ruth method.

(e) Cotton impaction method with fixation in abduction.*

(f) Operative treatment.

There is something to be said for each method listed, though no one, apparently, is using Senn's scheme today. But not one of the six methods is a desirable routine for all cases. Routine must vary with the case.
